Critical infrastructure systems, such as water and electricity, are important for society and national defense. There is a need for network analysis tools that allow analysts to study potential scenarios to discover vulnerabilities, assess consequences, and evaluate effective solutions to overcome network weaknesses. In order to be useful, models of critical infrastructure systems need to be realistic, both geospatially and functionally. The objective of this thesis is to bridge the gap between geospatial and functional network analysis by developing a software tool that allows users to create and edit networks in a Graphical Information System (GIS) visual environment, and then also run and view the results of functional network models. Our primary contribution is to provide an easy-to-use, graphical interface in the form of a plugin that allows users, regardless of their network expertise, to create networks and exercise network flow models on them. We demonstrate the usefulness of our plugin through the analysis of a fictional case study with a realistic Internet infrastructure. We run several minimum cost flow models with simulated network attacks to assess the robustness of the network.
A GEOGRAPHIC AND FUNCTIONAL NETWORK FLOW ANALYSIS TOOL

ABSTRACT

Critical infrastructure systems, such as water and electricity, are important for society and national defense. There is a need for network analysis tools that allow analysts to study potential scenarios to discover vulnerabilities, assess consequences, and evaluate effective solutions to overcome network weaknesses. In order to be useful, models of critical infrastructure systems need to be realistic, both geospatially and functionally. The objective of this thesis is to bridge the gap between geospatial and functional network analysis by developing a software tool that allows users to create and edit networks in a Graphical Information System (GIS) visual environment, and then also run and view the results of functional network models. Our primary contribution is to provide an easy-to-use, graphical interface in the form of a plugin that allows users, regardless of their network expertise, to create networks and exercise network flow models on them. We demonstrate the usefulness of our plugin through the analysis of a fictional case study with a realistic Internet infrastructure. We run several minimum cost flow models with simulated network attacks to assess the robustness of the network.

ACKNOWLEDGMENTS

First, I must thank Professor David Alderson. I was truly fortunate to have him as one of my advisors. I cannot express enough how grateful I am for his guidance and knowledge throughout this thesis project. He made this large undertaking into something I was able to manage and complete.

I would also like to thank Professor Rudolph Darken for his continued support and constant optimism. He kept me focused while working on this project. I hope this plugin becomes something that is used often throughout the Operations Research department.

Last, I would like to thank Erik Johnson and his team for answering my programming questions. I greatly appreciated their willingness to help me. I also really enjoyed sitting in on the weekly developer meetings.
I. INTRODUCTION

Presidential Policy Directive 21 (PPD-21), titled “Critical Infrastructure Security and Resilience” and signed February 12, 2013 lists 16 infrastructure sectors that are vital to national security (White House 2013). These infrastructures include water, energy, transportation, banking and finance, and information and telecommunications, among others.

PPD-21 tasks the Department of Homeland Security (DHS) with increasing the security and resilience of our nation’s critical infrastructures. Commercial enterprises are also interested in improving the efficiency and reliability of their private systems. Infrastructure systems are prone to many disruptions, both non-deliberate and deliberate. Non-deliberate mishaps may result from weather, technical failure, and operator error whereas deliberate acts include terrorism and vandalism. Knowing where infrastructure systems are vulnerable to deliberate and non-deliberate disruptions is exceedingly useful to increase resilience.

Most of the 16 critical infrastructure sectors are made up of systems that are networks or key components in a larger infrastructure network. The interdependencies of these network systems are so complicated that studying each critical infrastructure’s resilience to disruptive events requires network analysis tools. Network analysis tools allow operators to experiment with potential scenarios to discover vulnerabilities, assess consequences, and evaluate effective solutions to overcome network weaknesses.

To be useful for critical infrastructure systems analysis, models must be realistic, both geographically and functionally. Geographic realism provides analysts with the spatial relationship between system components. Geographic representations of infrastructures are often simply maps showing the locations of physical structures. Functional realism models how the system works relying on the interactions between the components of a network. This requires detailed data. But it is often the case that real network data is kept private for security and proprietary reasons. Researchers often work around this by inferring a network’s topology through experimentation or open source
data collection (e.g., Alderson et al. 2005), but the lack of realistic network topology data remains a problem nonetheless. Without the ability to run analytic techniques on real networks, these techniques are of limited value. Moreover, the lack of accessible, real network data means that there are no benchmarks for the analysis models used on simple, “toy” networks. In addition, new models cannot be validated or tested for accuracy before they are used to assess a real network. These models rely heavily on network theory but have scarcely been verified in modern applications.

There is a large focus on Geographic Information Systems (GIS) when cataloging and studying critical infrastructures (Federal Geographic Data Committee 2014). A GIS system visually represents the infrastructure on a map offering the geographic realism necessary for some types of network analysis. One problem with the exclusive use of GIS for studying critical infrastructure is that these representations are no more than drawings. The functional relationships between the images representing system components and the images representing the links between them are not represented. Although they are useful inventories of geographic data, GIS models typically cannot be used for functional network analysis, including concrete ‘what if’ scenarios.

To address this shortcoming, there is considerable work being done on functional models of key infrastructure networks. Researchers at the Naval Postgraduate School’s Department of Operations Research and Center for Infrastructure Defense have studied critical infrastructures through the use of attacker-defender models (e.g., Brown et al. 2005, 2006; Barkley 2008; Dixon 2011; Crain 2012). These models use game theory and optimization models to find worst-case disruptions to infrastructure function, accounting for the ways in which infrastructure owners and operators try to adapt to disruptive events. Like GIS models, attack-defender models have great use, but also significant limitations. For example, applying attacker-defender analysis to an infrastructure network is not easy and typically requires domain expertise to build, execute and interpret. In addition, these models typically require expensive, proprietary software to be used. They manipulate problem data using simple text files for input and output, but they historically have offered little visualization of either input or output.
The objective of this thesis is to bridge the gap between geographic and functional network analysis. We aim to develop a tool that allows users to create and edit networks in a GIS visual environment and also allow them to run and view the results of functional models. Our goal is to “close the loop” between the network creation environment provided by GIS tools and the functional analysis tools provided by network models (see Figure 1).

![Diagram showing the loop between geographic and functional network model analysis.]

Figure 1. Our tool completes the loop between geographic and functional network model analysis.

We demonstrate the usefulness of this framework by creating a sample network and running realistic scenarios on it. Specifically, we model a fiber optic communications network in the Dystopia virtual environment, which is a fictitious example of a GIS environment. This network is functionally realistic, in the sense that it adheres to the technological constraints at work for real systems and it carries network traffic for realistic populations. Using a functional model, we assess the impact of losing one or more network connections, and we also evaluate the potential benefit of specific investments in component hardening, capacity expansion, or new network construction.
II. BACKGROUND AND RELATED WORK

We start by reviewing previous research in Geographic Information Systems (GIS) modeling and functional network analysis. Then we summarize recent work attempting to improve the limitations associated with each of these.

A. GEOGRAPHIC INFORMATION SYSTEMS TOOLS AND DYSTOPIA

The Federal Geographic Data Committee (FGDC) is an interagency organization that promotes the coordinated development, use, sharing, and dissemination of geospatial data. Geospatial information technology provides homeland security decision-makers with important information to handle disruptions that include natural disasters, terrorist attacks, and sabotage. The FGDC lists several major benefits of GIS data for homeland security applications: detection of weaknesses, preparedness for incidents, prevention of threats and attacks, protection against failure, and more effective response and recovery. (Federal Geographic Data Committee 2006)

Dystopia (Center for Homeland Defense and Security 2013) is a collection of geospecific metadata that creates a comprehensive virtual world. It was developed by the Naval Postgraduate School’s Center for Homeland Defense and Security (CHDS) to be a realistic, flexible scenario environment for educational exercises. These scenarios task students with finding solutions to the issues posed in the exercise. Dystopia is not a game itself, but a context for the games to be run. By definition, a dystopia is “a place where bad things happen”—a fitting name for a place where the scenarios are often full of destruction. As shown in Figure 2, Dystopia is an island annotated with detailed spatial GIS information. It contains many population centers divided by a national border.
Dystopia contains several GIS layers that include key infrastructure systems such as oil, power, water, important points of interest (e.g., commercial, education, government, military), and transportation infrastructure (e.g., railways, roads, and airports).

Dystopia’s usefulness stems from its realistic detail, while still being a fictitious world. This allows Dystopia to be used to practice real world scenarios without the complications of using real world data. The limitation of Dystopia is that it is merely a map with images on it. Zooming in reveals detailed roads and buildings, but they are not represented by anything other than the lines drawn on the screen. This thesis work
B. MODELS OF INFRASTRUCTURE FUNCTION

Functional models allow network analysts to represent their networks as mathematical objects that can be used to run simulations. These simulations give insight to network efficiency, redundancy, and security—exactly the attributes that network operators constantly review. One class of functional models is based on the use of network flows as described by Ahuuja, Magnanti, and Orlin (1993). There exists a variety of network flow models, such as minimum cost flow, shortest path, maximum flow, assignment, transportation, circulation, and multicommodity flow. This thesis focuses on minimum cost network flow problems. Like the name suggests, a minimum cost flow problem seeks the least costly way to transfer a commodity from one node to another, taking into consideration the cost and capacities of each arc that lies in between. Minimum cost models can be applied to any commodity distribution service, making these models extremely useful.

Throughout this thesis, a network will be described by a set of nodes and a set of directed arcs. Nodes are the connection points, and arcs are the one-way links between them. Consider an electric power system as an example; power plants can be represented by nodes and power lines can be represented by arcs. Networks are more than simple mathematical graphs because nodes and arcs have attributes associated with them. These attributes are customizable and provide the flexibility for network models to be applied to most any infrastructure network. Using again the example of the electric power grid, power station nodes may have the following attributes: power output capacity (watts), cost (dollars/year), fuel type (coal/nuclear), etc. Power line arcs may also have several attributes: length (miles), voltage (volts), current (amperes), etc. These attributes are different than the node and arc attributes in the water sector and those in the information technology sector.

Attacker-defender models combine game theory with network flow models to provide worst-case modeling scenarios. They assume an intelligent attacker, able to
choose a point of weakness to attack. The defender tries to minimize the effects of these attacks through security measures such as network hardening and redundancies. We look at previous work applying attacker-defender models to communication networks in order to give insight into extending the GIS’s additional functionality for vulnerability analysis.

Barkley (2008) uses an attacker-defender model to analyze communication networks based on the Internet Protocol (IP). Assuming an IP infrastructure, Barkley considers point-to-point traffic or “flows” and looks at both extremes of packet routing: shortest path and maximum flow. Traffic on a shortest path infrastructure will travel the smallest distance (fewest hops, lowest “mileage”) from point ‘A’ to ‘B’. In contrast, a maximum flow problem takes advantage of all available paths and capacities to transfer flows from ‘A’ to ‘B’. Barkley compares both routing implementations and the optimal interdiction to most significantly reduce the flow rate.

Crain (2012) assesses the robustness of the present day undersea cable infrastructure. He considers the redundancies of more than 220 real cable systems, and he uses attacker-defender models on these networks to test redundancy and look for weaknesses. Crain uses gravity models (see Alderson et al. 2006 for a review) to generate a realistic traffic matrix. Gravity models in a networking sense are analogous to the law of gravitation in physics. Physics states that the larger the mass of an object, the higher the force of gravity on surrounding objects. Using a city’s population analogously to mass we are able to estimate the traffic demand across a link.

Most network models consider only a single infrastructure in isolation. For example, a water system might be represented as a network of pipes (arcs) and pumps (nodes). These models often do not consider the interdependencies between infrastructures. Water pumps require electricity; therefore, the model analyzing the robustness of the water system should have some notion of the robustness of the electrical system that powers it. Dixon (2011) focuses on these interdependencies and the application of attacker-defender models to interdependent networks. Although this thesis work does not include details for specific interdependent layers, we used Dixon’s work to lay the groundwork for the format and layer requirements.
Functional models can be extremely helpful to analyze networks for weaknesses; however, they traditionally have suffered from several limitations. First, functional models often lack the geographical relationships within networks found in GIS models. Second, many functional models rely on local computation using expensive third-party software licenses, complicating the already intricate workflow. Last, these models are not modular themselves making it difficult to transfer the output of one model to the input of another. This lack of modularity also prevents model creators from adapting existing models to more complex applications. Model makers must then create each model entirely themselves.

C. COMPLETING THE LOOP

Previous work has looked into simplifying the application of functional models on networks. Gun (2013) worked extensively with the General Algebraic Modeling System (GAMS 2010) computation engine. His goal was to create a cloud implementation for the GAMS software where users could interact with a web interface rather than a program running locally. This approach is similar to the goal of this thesis: automating the mathematical model in a simple user interface. Gun’s major focus was model integrity checking and visualizations. The importance of model integrity checks is paramount, as this process has become extremely modular. There are many potential breakpoints if each process isn’t verified properly. Gun’s idea of visualization is different from the visualization expected in this thesis. While Gun expected immediate visualization of the GAMS output, he considered only simple line, bar and pie charts. While these visualizations can be a nice way to see changes in data, viewing the effects of a model actually on the network is often more useful. For example, we consider the use of color gradients for a particular attribute to be reflected on the network for simple and easy visualization.

This thesis work relies heavily on Quantum GIS (QGIS 2012) to model our simulated networks. QGIS is a free, open source Geographic Information System software suite. We ran version 1.8.0-Lisboa for plugin compatibility reasons.
III. ARCHITECTURE AND IMPLEMENTATION

The primary contribution of this thesis is the design and development of an extension to an existing plugin for Quantum GIS that allows users to run functional models on networks displayed in a GIS editor. Our modified plugin combines the benefits of the geographic information contained in the GIS metadata and the functional relationships between the attributes that make up the nodes and arcs of the network. This chapter first describes the network flow model we use to validate our workflow, and then it explains how our plugin uses the model’s output to visualize the results.

A. NETWORK FLOW MODEL

Our proof of concept network analysis uses a minimum-cost network flow model described in Ahjua et al. (1993). This formulation is described in depth in Crain (2012), and for the most part we treat it as a black box. The model is run using GAMS and solved by CPLEX (ILOG 2007). The model requires an input network with specific attributes associated to the nodes and arcs. Nodes must have unique names, while arcs are described in terms of a “head”, “tail”, “capacity”, and “cost”. The model also requires a traffic matrix specifying the amount of traffic traveling from each node to every other node. This information is supplied to GAMS using comma-separated-value (CSV) files.

Consider the simple network illustrated in Figure 3 as our example case.

Figure 3. A simple network to run the network flow model.
For simplicity, we assume that every arc in this network has a capacity of 6 and a cost of 1. Table 1 shows the traffic matrix that is used. The units of flow in this simple example are notional.

Table 1. Traffic matrix for the network.

Table 2 shows the flows that minimize the routing cost while adhering to arc capacities. This information is returned after running the flow model on this simple network.

Table 2. The output of the network flow model on the simple network in Figure 3 based on the traffic demands in Table 1.
Even for this simple case, the results in Table 2 are not easy to understand; we see the lack of visualization of the results for our network. Instead of reading the flow results from a table we would like to see the flows on the network itself, as in Figure 4. Our plugin aggregates this output, and updates the attributes within the visualization tool to show changes of flow.

Figure 4. Our simple model redrawn to show network flow in a more intuitive manner.

B. PLUGIN FUNCTIONALITY

We extend the Quantum GIS ArcMaker plugin developed by Johnson et al. (2013) to include support for network simulation allowing users to run mathematic models on layers within QGIS. Figure 5 shows the extended plugin. The ArcMaker plugin allows users to create nodes and arcs that are logically connected. Moving a node also redraws all of the arcs connected to that node in order to stay connected to it. This is a feature that QGIS is currently missing, but a necessity when creating and editing complicated networks.
Figure 5. Quantum GIS with the ArcMaker plugin.

Figure 6 shows the additional functionality to the ArcMaker plugin. The plugin is very simple from the user’s perspective. We allow the user to choose from one of the installed network models from the dropdown menu, and then run it on the currently selected node and arc layer. Choosing to keep the input and output files prevents the plugin from deleting them upon uploading the data back into QGIS. This gives the user a chance to debug unusual behavior. In the case of the network flow model, the traffic matrix is a required file that is not produced by QGIS. When running the model, the plugin will prompt the user to load one of these files. The plugin will continue to use this file until the user selects “Reset Required Files”. This gives the user the chance to choose another file in the case that the traffic matrix changed.
Once the run button is clicked, the plugin starts the loop illustrated in Figure 7. Simply, we turn the QGIS layer attributes into GAMS input, run the selected model through GAMS, and then reload the model’s output as the new attributes in QGIS.
graphical user interface (GUI). The GAMS box is the computation engine for the specified model. In this thesis, we treat this process as a black box to which we feed input and receive output. However, there are many complicated steps described in Crain (2012).

C. PLUGIN IMPLEMENTATION

We extend the ArcMaker plugin by inserting our own Python methods into the source code. Here is a description of each of the important steps throughout the flow model shown in Figure 7:

1. The first step is to read a configuration file, an Extensible Markup Language (XML) file that contains all of the necessary information describing the input and output of the model. Each model has its own configuration file inside the ArcMaker plugin in a directory with the model’s name. The configuration file contains the filename of the GAMS model, the filenames and necessary attributes for the GAMS input, and a description of the GAMS output. Parsing this XML configuration file allows the plugin to create the input files with the correct format. Missing one comma or new line can cause the plugin to crash. An example configuration file is in the Appendix.

2. When the Run button is selected, all of the attributes from the chosen node and arc layer are written to Comma Separated Value (CSV) files. CSV is used because GAMS takes its input and writes its output in the CSV format. The plugin contains the active node and arc layer in the top two dropdown menus. The node and arc layer’s attributes are written to separate CSV files. The attributes in these files will be used to create the resulting input files for GAMS.

3. Based on the configuration file, the model-specific input files are created. We iterate through the input files contained in the configuration file, writing them as we go using the attributes in the output of step 2.

4. With all of the input files in place, GAMS is executed. GAMS reads the CSV files as input and generates CSV files as output. The configuration file contains all of the information needed to read the output.

5. The output of GAMS is compared against the original input. We iterate through the GAMS output and the original attributes contained in step 2’s output. Comparing these attributes, we create a “changes” file to summarize the output.

6. Within QGIS, we upload the new attributes from the changes file. Depending on the visualization style settings, the changes can be viewed instantly if the style is set to reflect a gradient on the attribute that the model changed.
D. PLUGIN USEFULNESS

The plugin overcomes the limitations of GIS and functional network analysis by combining the benefits of each. There is now a standalone environment for creating and editing networks, as well as running network flow models on them. This connection eliminates the need for users to run models using Excel files. Instead, the plugin handles the data conversion between QGIS and GAMS.

The plugin is intended to be simple and robust. There are integrity checks for every step to prevent a user from trying something that will not work or cause an error. Since we treat GAMS as a black box, there is a strong potential for errors if passed the wrong input. We monitor the GAMS output closely and pass as much information as possible back to the user in the event there is a problem. This puts a lot of the responsibility on the GAMS model creators to develop models that are robust to crashes.
IV. CASE STUDY: FIBER OPTIC COMMUNICATIONS BACKBONE IN DYSTOPIA

One of the major goals of this thesis is to create a realistic Internet infrastructure to test the plugin functionality discussed in the previous chapter. Even with its many detailed layers, Dystopia is missing a cyber infrastructure. We aim to draw a realistic, backbone Internet infrastructure on Dystopia on which to run our network flow models.

A. METHODOLOGY

1. Network Design Considerations

Figure 8 shows a plausible fiber optic communication network for Dystopia. It contains 18 nodes and 24 bidirectional arcs that collectively represent hundreds of miles of backbone fiber cable, both over land and undersea.
Its design reflects an approximate economic cost associated with laying this fiber down, as links are very expensive. Fewer and shorter links save Internet Server Providers (ISPs) money, while many longer links provide more robust, resilient networks. Balancing redundancy and monetary expense is a tenet held closely for all ISPs. This Internet infrastructure focuses solely on the network core. To achieve this, we closely followed the first principles approach discussed in Alderson et al. (2005) describing the tradeoff between bandwidth and number of links. As noted in that work, routers nearest the core of a network tend to have fewer connections, but faster throughput (Alderson et al. 2005). This network also conforms to the general principles of network design identified by Topology Zoo and the BRITE Topology generator (Byers et al. 2014; Bowden 2013). Both projects aim to accurately map the network topologies behind the Internet.

We currently show only the core routers and the backbone links that connect them. With this example, this project provides a general proof of concept that could be extended to create a very detailed, low-level network within one city. The network’s granularity could even be so detailed to show individual users as nodes connected to the network.

Fiber optic cables can be bidirectional meaning they simultaneously send data in both directions. If being used in a single direction, fiber cables almost certainly exist adjacent to a parallel link (Strachan 2005). We represent this in Quantum GIS (QGIS) using two arcs (one in either direction) between nodes. Figure 9 shows two arcs drawn closely to represent bidirectional flow between two nodes.

Figure 9. Bidirectional representation of arcs in Dystopia.
2. **Network Attributes**

With the network drawn as layers on Dystopia in Quantum GIS (QGIS), our next step is to analyze it using the network flow model discussed in Chapter III, Section C. Before we can run our analysis, we need to specify the input data for the problem.

**a. Traffic Matrix**

First, we must specify a traffic matrix for the amount of traffic traveling from one node to every other node. We represent this traffic in a two-way table based on a gravity model (Alderson et al 2006). Our gravity model is based on the estimated population surrounding each node. Since Dystopia is completely fictional, there is little information about city population. Therefore, we assign city populations based on Dystopia’s total population of more than 400,000 people and a few specified city populations. We approximate the populations around the other nodes based on the infrastructure surrounding them. Residential areas receive higher populations than commercial areas.

After assigning populations, we consider the number of Internet users. Dystopia has a national border splitting the island into a northern and southern region. Some of Dystopia’s scenarios consider the southern country to be the United States and the northern country to be Mexico. Using data from the World Bank, we treat only 38.4% of the population in Mexican cities as Internet users and 81% of the population around nodes in the United States as Internet users (The World Bank 2014). We recognize that these percentages may be low, as they take into account the entire country of Mexico and the United States, rather than the percentage of Internet users within cities. We accept this oversimplification, as this scenario is really only a proof of concept and the numbers are fictional anyway.

Based on the number of Internet users per node, we estimate the amount of traffic each node receives. We use statistics released by AT&T (AT&T 2014) and Comcast XFINITY (Comcast 2014) to roughly estimate the traffic demanded by each Internet user each month. We assume an estimated 21 GB of data demanded each month based on an assumed 30 days per month. These steps give a figure for GB of traffic per day for each node. Table 3 shows the progression from population at each node to GB of traffic per
day on each node. The figure denotes undersea nodes as blue, nodes in the United States as red, and nodes in Mexico as green. Undersea nodes have a zero population and therefore have a zero demand for data.

The figure denotes undersea nodes as blue, nodes in the United States as red, and nodes in Mexico as green. Undersea nodes have a zero population and therefore have a zero demand for data.

</table>

Table 4. Notional traffic matrix based on assumed populations. The values in this matrix represent relative demands. Absolute demand is scaled by network capacity.

Our traffic matrix’s gravity model is a simplification of actual network traffic demand. Data content providers like Akamai (Akamai 2014) and Google (Google 2014) place large server farms and data caches near population centers to reduce the need for
heavy backbone traffic. *Wired.com* reports that 25% of North American’s Internet Traffic is served by Google (2013). These local caches support huge data streams. Servers also have very asymmetric traffic flow, as the traffic outbound is often several times larger than the request traffic; this is not represented in our traffic matrix but could be incorporated. Another simplification is the time of day. Network flow changes drastically during the progression of the day. Network analysts are most interested in studying peak traffic, as this is when they would see the greatest number of bottlenecks in their routing. According to iMediaConnections (Harlin 2012), this peak happens at four o’clock in the afternoon.

*b. Arc Capacity*

For simplicity, we assume all arcs have the same capacity. We calculate the capacity in Gigabytes per day, as this is the unit we use for our traffic demand. According to Network Dictionary, Optical Carrier 192 (OC-192) was the most common fiber used for backbones by large Internet Service Providers in 2006. OC-192 has a capacity of 9.6 Gigabits per second (Gbps) (Dong 2007). After unit conversion, our capacity is 103,680 Gigabytes per day.

c. *Arc Cost*

Since arc cost is the notional “price” of traversing an arc, it can vary greatly on the networked infrastructure. Since we are modeling IP traffic traveling over fiber optic cables, it is the latency between nodes that determines the cost. Network latency is caused by delays in routers, while the transmission time of data through cabling is often negligible. Therefore, when determining the cost of each arc, we only count the number of “hops” over routers. Thus we make each arc cost 1, regardless of the length of the link connecting the two nodes.

**B. NETWORK FLOW ANALYSIS**

Our next step is to apply the minimum-cost flow model to our network. Again, we use the minimum-cost flow model from Crain (2012). We consider several scenarios, each with one or more variations. First, we consider a base case to show the network
under normal conditions. Second, we look at the case where an arc is removed. Third, we look at the case where a particular node sees a large increase in traffic demand. Last, we look at the case where a new arc is added. In each of these network manipulations, we are interested in how the flow of traffic is affected and redirected to compensate for the changes.

1. Base Case

We begin our analysis by studying normal traffic through an undisturbed network to give us a base case to compare the more interesting cases. Figure 10 shows our network in QGIS after running the minimum cost network flow model with data defined in the previous section. We use QGIS’s style feature to classify and color code the arcs based on their flow attribute. Throughout this thesis, we use a graduated color scheme where dark red arcs represent those with the highest flows, and lighter, yellow arcs represent those with smaller flows. Applying this style makes it simple to visualize the flows, relative to each other.
Figure 10. Dystopia’s normal network flows with a graduated color scheme after running the minimum cost network flow model with our traffic matrix and arc attributes.

The relative flows shown above are exactly what we expect for the GAMS input. We see higher traffic flow between the population centers around nodes n2, n3, n4 in the south, and nodes n13, n14, n15, n16 in the north. Table 5 represents this flow information as a matrix with units Gigabyte per day (GB/day). Empty cells show there is no arc between those two nodes.
Table 5. Node to node network flows for Dystopia’s undisturbed IP network.

We compare the results of future scenarios against these flows in order to understand how the network is redirecting traffic. Comparing the average link utilization across all arcs as well as the amount of dropped traffic reveals an easy comparison for our network disturbances. We calculate link utilization by dividing the average flow over all links by the capacity of one link. The average link utilization for the base case is 47.74 percent with no dropped traffic.

2. Deleted Arc

We make the assumption that an interdicted arc will completely disrupt that link’s flow in both directions. Our minimum network flow model is instrumented to find the minimum set of flows, even in the case where some arcs are interdicted. We use GAMS to enumerate each possible interdicted arc, and to compute the minimum-cost solution for each. We do this for one and two arc failures seeking, as an adversary would, the maximum disruption.

a. Single Interdictions

Table 6 shows the results for single interdictions sorted by severity. While most single failures result in no traffic loss, several large impacts on traffic flow. Specifically,
there are four arcs (n1-n2, n1-n8, n3-n14, n4-n5) that yield the most dropped traffic. A fifth arc (n5-n6) leads to nearly as much dropped traffic.

Table 6. The amount of dropped traffic after a single interdiction.

We show two results from Table 6 in more detail. We start by visualizing the effects of deleting arc (n3, n14). We “delete” the arc by setting its capacity to zero in our QGIS editor. This is functionally equivalent to deleting the arc; however, it prevents the user from having to redraw the arc to bring it back online.

Figure 11 shows how the traffic flow is redirected after losing the crucial connection from the southern city (n3) to the northern city (n14).
Figure 11. Dystopia’s network flows after a single interdiction between nodes n3 and n14.

Notice the increased traffic rate through the undersea cables traveling on the eastern coast. The traffic between n1 and n2 nearly quadrupled. Table 7 shows the new flow matrix in GB/day. The highlighted zeros show the absence of flow traversing the interdicted links. This single interdiction raised the average link utilization to 63.04 percent and caused 194,040 GB of traffic to be dropped each day.
Table 7. Node to node network flows in Dystopia after a single interdiction between nodes n3 and n14.

In the same way, we delete the arc between nodes n4 and n5. Figure 12 shows the resulting network flow as displayed in QGIS. Similar to the previous case, we observe traffic rerouting around the disconnected arc through the undersea cables connecting nodes n1 and n8.
Figure 12. Dystopia’s network flows after a single interdiction between nodes n4 and n5.

This disruption results in the flow matrix displayed in Table 8. Once again, the highlighted cells represent the arcs that have been deleted.
Table 8. Node to node network flows in Dystopia after a single interdiction between nodes n4 and n5.

Deleting the arc connecting n4 to n5 causes the average link utilization to increase ten percent to 57.74 percent from the base case utilization rate and for the network to drop 194,040 GB of traffic per day.

b. **Double Interdictions**

Next we look at cases involving the simultaneous loss of two links. Using the same method to determine the worst-case losses, we find the worst-case double interdictions to be removing links (n1,n8) and (n4,n5) or (n1,n8) and (n3,n14).

Deleting the links (n1, n8) and (n4, n5) results in the network flows depicted in Figure 13. As we expect, the traffic demand is placed almost entirely on the arc connecting n3 and n14 as the southern city (n3) has lost its other two connections to the rest of the island. Table 9 shows the flow matrix after these two arcs are lost.
Figure 13.  Dystopia’s network flows after a double interdiction between nodes n1, n8 and n4, n5.

Table 9.  Node to node network flows in Dystopia after a double interdiction between nodes n1, n8 and n4, n5.
We see huge increases on the remaining arcs. The link connecting the south (n3) to the north (n14), increases from 10,410 GB/day in the base case to 25,365 GB/day. This network configuration yields an average link utilization of 71.35 percent with 401,400 GB per day of dropped traffic.

Next we delete the links between nodes n1, n8 and nodes n3, n14. The result is shown in Figure 14. Similar to the previous interdiction, the highly populated southern city (n3) relies on one link (n4, n5) to pass traffic. Table 10 shows the resulting flow matrix from this double interdiction.

Figure 14. Dystopia’s network flows after a double interdiction between nodes n1, n8 and n3, n14.
Table 10. Node to node network flows in Dystopia after a double interdiction between nodes n1, n8 and n3, n14.

As expected, we see a huge increase on the link from node n4 to node n5. This link goes from passing 14,365 GB per day in the base case to 25,365 GB per day. This case increases the average link utilization to 70.79 percent and causes 401,400 GB per day of dropped traffic.

Both Table 9 and Table 10 show an interesting case. Notice there are zeros outside the highlighted, deleted arcs. Deleting arc (n1,n8) prevents all traffic from traversing through (n1,n2). Node n1 does not have a population because it is undersea cable station. Since it can no longer pass traffic to node n8, there is no reason for traffic to be sent to it.

We show the capability of deleting arcs using our plugin and its effects on our network in Dystopia. The process is very simple from the user’s perspective. Deleting an arc consists of setting its capacity to zero, saving the changes, and then running the model. The new visualization will refresh automatically.

3. Increased Demand

In this scenario, we consider changes to our traffic matrix. First, we double the traffic demand at nodes n14, n15, and n16. Then we look at the difference after tripling the original demands in these three nodes.

Table 11 shows the new traffic matrix used in the next simulation. Notice the increases in demand under nodes n14, n15, and n16.

Table 11. The traffic matrix after doubling the demand in nodes n14, n15, and n16.

Figure 15 shows the result of running the flow model on our original network with the new traffic matrix. Table 12 shows the resulting flow matrix.

![Figure 15. Dystopia’s network flows after doubling the demand in nodes n14, n15, and n16.](image)
Table 12. Node to node network flows in Dystopia doubling the demand in nodes n14, n15, and n16.

This change produces relatively small changes to the base case’s flow matrix. It is apparent that the links connecting to the nodes with doubled demand did see an increase in flow, however there was not a tremendous difference. The network did see an increase in average link utilization with 58.93 percent and 109,444 GB of dropped traffic per day.

In order to see a larger difference, we now triple the original demand for nodes n14, n15, and n16. Table 13 shows the traffic matrix used in this simulation. Figure 16 shows Dystopia after running the second scenario where we increase demand.

Table 13. The traffic matrix after tripling the demand in nodes n14, n15, and n16.
Figure 16. Dystopia’s network flows after tripling the demand in nodes n14, n15, and n16.

Table 14 shows the resulting flow matrix. As expected, we see this traffic matrix change make a bigger impact throughout the entire network than in our last scenario. Average link utilization is now up to 70.48 percent. A large increase considering we only tripled the demand in three of our 18 nodes. This configuration also causes 116,280 GB of traffic to be dropped each day.
Table 14. Node to node network flows in Dystopia tripling the demand in nodes n14, n15, and n16.

4. Added Arc

As our last scenario, we consider the impact of adding an arc to the base case network. First we add an arc between nodes n3 and n10. The resulting visualization is displayed in Figure 17. Table 15 shows the new flow matrix. The highlighted cells are the new arcs and their respective flows.
Figure 17. Dystopia’s network flows after adding an arc between nodes n4 and n10.

Table 15. Node to node network flows in Dystopia after adding an arc between nodes n4 and n10.

</tbody>
</table>
As we expect, adding this arc decreases the network utilization. This change causes the percent utilization to drop from the base case’s 47.74 percent to 39.31 percent. Obviously adding this arc did not cause dropped traffic.

Next, we add an arc from node n3 to node n15 in an effort to reduce the traffic traveling from n3 to n14. Figure 18 shows the result. Table 16 shows the result of the addition of this new arc.

Figure 18. Dystopia’s network flows after adding an arc between nodes n3 and n15.
Similarly, we see decreases in the flow of several arcs. This addition brings the average link utilization down to 44.98 percent and does not cause any traffic to be dropped.

5. Summary of Results

We looked at three cases of network manipulations: arc deletion, change in demand, and arc addition. Figure 19 shows a summary of link utilization for each of our test cases alongside our base case. Figure 20 shows a summary of dropped traffic for each of our test cases.

Table 16. Node to node network flows in Dystopia after adding an arc between nodes n3 and n15.
Figure 19. Summary of average link utilization across network scenarios.

Figure 20. Summary of total traffic dropped across network scenarios.

Our addition to QGIS allows us to easily modify the network we are analyzing. After drawing a new arc, deleting an existing arc, or modifying the traffic matrix, the user simply has to select the run button to recompute all of the flow information, which is instantly reflected in the visualization.
V. CONCLUSION

A. CONTRIBUTION

Our primary contribution in this thesis is to provide an easy to use, graphical interface that allows users, regardless of their network expertise, to create networks and run models of system function on them. Doing so connects the benefits of the geographic information system’s visualization with the functional modeling capabilities of a network’s metadata. Users are now able to run these tests with one mouse click. This proves to be a much easier solution than the tedious task of manually generating input data and reading output data as text only. We also show the success in our attempt by applying this additional functionality to a realistic network we built in the fictional world of Dystopia.

Our case study applies the network flow model to the Internet infrastructure within Dystopia, but shows that we can just as easily apply this network building procedure to a variety of the critical infrastructures.

Not only is switching network infrastructures easy, applying network analysis to real world applications is just as simple. We create our Internet backbone network on a background layer of Dystopia, but we are equally capable of creating, for example, the high-level water infrastructure of Los Angeles on a map. The process is the same and can be applied to any networked infrastructure study.

B. FUTURE WORK

While our contributions are exciting in themselves, they open the door to many new projects. Currently, GAMS is required to be installed and licensed locally to run any GAMS model. A future step is to run a server that receives requests to run a model on files submitted to it then passes the input back to the client computer. Running the model on a server simplifies the installation process of the required tools, as GAMS would no longer be necessary.
This work analyzes networks independent of other networks. In reality, networks are interlaced with dependencies. For example, most network infrastructures rely on electricity. Therefore a water network, equipped with pumps and water stations are only effective if they have the energy to run them. Adding this functionality to the models that GAMS runs is a necessary first step before incorporating it to QGIS and our plugin.

Since we only look at a high-level backbone of the Internet layer in Dystopia, one could continue drawing the intricacies of the network. This would include the network links down streets and into buildings. One could implement access routers to provide points of presence for the citizens of Dystopia. Since Dystopia is so large and complex, adding the detail necessary for wireless routers, and individual building’s access would be extremely time consuming. An alternative would be to pick a subsection of a city to implement this finer detail.

This thesis focuses on network flow models. We did not test this design on other models, but are confident it will extend easily to them assuming a configuration file can be created describing the input and output of the model. A next step here is to write configuration files for other models and test them with our plugin.

Another interesting problem relating to network modeling is wireless access points. Traditional networks have links and arcs that are static. Wireless technology allows nodes to dynamically change the network configuration. Representing this feature of wireless devices creates new challenges in simulating the behavior of these networks. We look to past work of Shankar (2008) and Nicholas (2009) could serve as starting points. We hope the network modeling technique described within this thesis serves as a step forward in those endeavors.
APPENDIX. DATA FILES

A. CONFIGURATION FILE

This Extensible Markup Language (XML) file contains all of the information needed to describe the Minimum Cost Flow model to the plugin. It contains the necessary attributes for arcs and nodes, where to find them, and how to rearrange them into the input to GAMS. It also contains the format of GAMS output for seamless transition back into QGIS for visualization.

```xml
<?xml version="1.0" encoding="UTF-8"?>
<OperatorModel name = "Min Cost" file = "MinCost.gms" results = "changes.csv">
  <ModelInput name = "nodes.csv" header = "0">
    <Attribute name = "node" source = "nodes_all.csv"/>
  </ModelInput>
  <ModelInput name = "arcs_data.csv" header = "1">
    <Attribute name = "tail" source = "arcs_all.csv"/>
    <Attribute name = "head" source = "arcs_all.csv"/>
    <Attribute name = "capacity" source = "arcs_all.csv"/>
    <Attribute name = "cost" source = "arcs_all.csv"/>
  </ModelInput>
  <ModelInput name = "arcs_set.csv" header = "0">
    <Attribute name = "tail" source = "arcs_all.csv"/>
    <Attribute name = "head" source = "arcs_all.csv"/>
  </ModelInput>
  <ModelInput name = "traffic_matrix.csv" header = "2" external="1"/>
  <ModelOutput name = "flows.csv" header = "1">
    <Attribute name = "tail" source = "arcs_all.csv" constant="1"/>
    <Attribute name = "head" source = "arcs_all.csv" constant="1"/>
    <Attribute name = "flow" source = "arcs_all.csv" constant="0"/>
    <Attribute name = "destination"/>
  </ModelOutput>
  <Layer>
    <Node output = "nodes_all.csv">
      <Attribute name = "node"/>
    </Node>
    <Arc output = "arcs_all.csv">
      <Attribute name = "tail"/>
      <Attribute name = "head"/>
      <Attribute name = "capacity"/>
      <Attribute name = "cost"/>
      <Attribute name = "flow"/>
    </Arc>
  </Layer>
</OperatorModel>
```
B. INPUT FILES

The files below represent the GAMS input for running the minimum cost flow on the sample network in Figure 3.

1. **arcs_set.csv**

   Arcs_set.csv lists the arcs that make up the network. They are listed from the “tail” node to the “head” node.

   n1,n2  
   n1,n3  
   n2,n1  
   n2,n3  
   n3,n1  
   n3,n4  
   n4,n2  
   n4,n3

2. **nodes.csv**

   Nodes.csv contains the list of nodes in the network. The names must be unique.

   n1  
   n2  
   n3  
   n4

3. **arcs_data.csv**

   Arcs_data.csv contains the attributes describing the arcs in the network.

   tail,head,capacity,cost  
   n1,n2,6,1  
   n1,n3,6,1  
   n2,n1,6,1  
   n2,n3,6,1  
   n3,n1,6,1  
   n3,n4,6,1  
   n4,n2,6,1  
   n4,n3,6,1

4. **traffic_matrix.csv**

   Traffic_matrix.csv is a two way table listing the demands between each node pair.

   ,n1,n2,n3,n4  
   n1,-8,2,2,4
C. OUTPUT FILE: FLOW.CSV

Flows.csv is the output from GAMS. We use the flow column to determine the new flow between the arc from the “tail” node to the “head” node.
