ABSTRACT

During launch of aircraft off of a carrier deck, steam leakage is sometimes ingested into the aircraft's engine and may cause a compressor stall or "pop-stall". As the US Navy prepares to field the single engine F-35C Joint Strike Fighter, it becomes necessary to investigate the phenomenon known as "pop-stall". In the present study, steady-state as well as transient measurements prior to and during a steam induced rotating stall were taken. Changes to the honeycomb altered the performance characteristics of the Transonic Compressor Rig and needed to be remapped in order to determine a new stall line as well as a peak performance criterion. Data was taken at 90 percent design speed as well as during a 70 percent steam induced stall with the aide of 9 Kulites at varying positions along the case wall. Data was reduced and analyzed through the use of a data acquisition and data reduction system.

ACKNOWLEDGMENTS

I would like to thank Professor Hobson for the amount of effort and time that he put in to help me complete my thesis. I would also like to thank John Gibson and Rick Still for their hard work and quick wit making the Turbopropulsion Laboratory a more enjoyable place to work. I have appreciated my time here and couldn't have asked for better people or a better place to work.

I. INTRODUCTION

As the United States Navy begins to transition to the F-35C Joint Strike Fighter (JSF) it becomes necessary that the phenomenon known as a "pop-stall" be resolved. A "pop-stall" occurs when the catapult-launch system on an aircraft carrier releases steam during a launch cycle. The steam is than ingested into the intakes of the aircraft, causing a fan or compressor stall and a possible total engine stall or "pop-stall". Experiments conducted at Naval Air Engineering Station Lakehurst with an F-18 demonstrated the relative susceptibility of the aircraft to "pop-stall" events. This susceptibility of the dual engine F-18 is of significant interest because as the Navy begins to transition to the single engine F-35C, the probability of a "pop-stall" occurring and causing a catastrophic loss of an aircraft increases.

The work done at the Turbopropulsion Laboratory (TPL) at the Naval Postgraduate School (NPS) focuses on the "pop-stall" problem with the use of the Transonic Compressor Rig (TCR). The transonic compressor fan stage was specifically designed for the Naval Postgraduate School to be used in the TCR by Sanger (1996) at the NASA Glenn Research Center (Ref. 1 and 2). These investigations conducted on the TCR are intended to improve the understanding of steam-induced stall.

The performance characteristics of the compressor in both the fan-stage as well as the rotor-only configurations were mapped with the data that was collected by Gannon, Hobson and Shreeve. This data was used to establish performance characteristics at 70%, 80%, 90% and 100% design speed prior to and during stall. (Ref 3-4). Unsteady pressure measurements at 60%, 70%, and 80% design speed were reestablished by Rodgers in 2003 (Ref. 5). Inlet and exit surveys at 70%, 80%, 90% and 100% design speed with a three-hole probe were conducted by Villescas (Ref. 6). Villescas determined the spanwise distributions of the rotor diffusion factor at choke, peak efficiency and stall while Brunner repeated the surveys with a 5-hole probe and determined the pitch angle and Mach number distributions in the inlet of the rotor (Ref 7). Payne took performance data at 95 percent speed, with a hot-film probe as well as Kulite pressure transducers in the case wall. He also took transient data from both the hot film and Kulite pressure transducers during steam induced stall at 70% speed (Ref 8).

Changes to the inlet and honeycomb have altered the performance characteristics of the Transonic Compressor Rig. The compressor performance was remapped in order to determine a new stall line as well as the peak performance criterion. In the current study, unsteady pressure measurements were established, with the installation of 9 Kulites at varying positions along the case wall. Data were taken at the 90% design speed as well as prior to and during a steam induced stall. Steam induced stall measurement were also taken at 70% speed to reestablish previously taken data to reflect alterations in the honeycomb. The data was then reduced and analyzed through the use of a data acquisition and data reduction system.

II. TRANSONIC COMPRESSOR

A. SANGER STAGE

The Sanger compressor stage was specifically designed for testing and assessment at the TCR using CFD techniques, while minimizing conventional empirical design methods. Figures 1 and 2 show a sectioned drawing and the rotor installed into the test rig, respectively.

Figure 1. Transonic compressor sectioned view

Figure 2. Rotor-only configuration of the transonic compressor rig (From Ref. 8)

The rotor had 22 blades and was made from a high strength aluminum alloy (7075-T6). For the present experiment, the rotor was tested with a parabolic spinner, which replaced the conical spinner used by O'Brien (Ref. 9).

For most of the previous studies the entire stage was evaluated. However, for the current study, the stator was removed and only the rotor was present to ensure the simplest configuration tested during steam ingestion. The design specifications for the Sanger Stage are given in Table 1.

Parameter	Value
Pressure Ratio	1.61
Tip Speed	33.02 m/s (1300ft/s)
Design Speed	27085 rpm
Design Mass Flow	7.75 kg/s (17.05lb/s)
Specific Mass Flow	170.88 kg/s-m ² (35lbm/s-ft ²)
Specific Head Rise	.246
Tip Inlet Relative Mach Number	1.28
Aspect Ratio	1.2
Hub/Tip Radius Ratio	.51
Rotor Inlet Ramp Angle	28.2
Number of Rotor Blades	22
Tip Solidity (Rotor)	1.3
Outside Diameter	0.2794m (11 inches)
Rotor Diffusion Factor – Tip	.4
Rotor Diffusion Factor - Hub	.47

Table 1.Sanger Stage Parameters

The Sanger stage represents characteristic of a first stage of a modern fan. The tip inlet relative Mach number is lower than most modern transonic compressors, however the blade loading is higher, which allows a pressure ratio of 1.56.

B. TRANSONIC COMPRESSOR TEST RIG

The Transonic Compressor Rig (TCR) test rig, as shown in Figure 3, was driven by two opposed-rotor air turbine stages, supplied by a 12 stage Allis-Chalmers axial compressor. The Allis-Chalmers compressor supplied three atmospheres of air pressure at a mass flow rate of 5 kg/s. Air was drawn into the TCR from the atmosphere through a throttle valve as shown in Figure 4. A five-meter long 46cm diameter pipe connected the settling chamber to the test compressor. The air would then flow through a nozzle, which was used for flow rate measurements and was exhausted back to the atmosphere. The rig's schematic is also shown in Figure 5.

Figure 3. Transonic Compressor in test cell with inlet piping removed (From Ref. 8)

Figure 4. Transonic Compressor Rig Schematic

C. STEAM INJESTION SYSTEM

The compressor rig and steam ingestion system is shown in Figure 5. Steam was generated by the SVS600 steam boiler and was directed through a 7.62 cm diameter pipe and vented to the intake plenum as can be seen in Figure 6. The SVS600 was capable of producing saturated steam up to a maximum working pressure of 1000 kPa or 1.4 kg/sec at 100 0 C and can be seen in Figure 7 (Ref. 9). In order to monitor the transient response of the steam pressure, a pressure transducer was installed into the steam pipe and can be seen in Figure 5. Two remotely-operated fast acting solenoid valves were used for releasing the steam into the intake plenum as well as for venting the pipe. Figure 7 shows the orientation of the steam pipe with respect to the intake plenum.

Figure 5. Transonic compressor rig with steam ingestion system

III. INSTRUMENTATION

A. KULITE PRESSURE TRANSDUCER

A Kulite miniature silicon pressure transducer, model XCQ-080-25, was used to obtain time-resolved pressure data. The probe was a miniature, semiconductor, strain gauge transducer which incorporated a fully active four-arm Wheatstone bridge dielectrically isolated silicon-on-silicon diaphragm. A diagram of the probe is given in Figure 8 and the specifications are given in Table 2.

Figure 8. Kulite XCQ-080 series transducer (From Ref. 5)

Input	
Pressure Range	1.7 atm 25 PSI

Thermal Sensitivity Shift	+- 1 % FS/100 F

Table 2.XCQ-080-25 Factory Specifications (From Ref. 5)

For the current study, 9 Kulite transducers had to be installed in the casing of the TCR. The full bridge Kulite Pressure Transducers were connected to the Hewlett-Packard E1529A Remote Strain Conditioning Unit, via a RJ-45 cable (Ref. 10). Figure 19 shows the correct set up of the Kulite wires and their corresponding RJ-45 pin assignments.

Figure 9. Kulite Connection to RJ-45 Plug (From Ref. 5)

The Kulite Pressure Transducer had four wires, a black, white, green, and red wire. The black wire was connected to pins 2 and 7, and the white was connected to pin 6. Pin 3 was connected to the green wire and pins 1 and 8 were connected to the red wire. Pins 4 and 5 were not connected to any wires.

B. INSTALLATION OF KULITE PRESSURE TRANSDUCER

Nine Kulites were connected to RJ-45 cables and were installed into aluminum slugs. The aluminum slug was originally designed by Vavra for unsteady pressure measurements of the Vavra stage, and can be seen in Figure 10 (Ref. 11).

Figure 10. Kulite Mounting Design

Once the nine Kulite pressure transducers were installed into the aluminum slugs they were mounted flush with the casewall. Figures 11 and 12 show the positioning of the Kulites relative to the casewall. The Kulite pressure tap locations were spaced one blade spacing apart and their corresponding locations across the blade were at 10.5%, 37%, 63%, and 89.5% axial chord. In addition a once-per-revolution speed pickup was used.

Figure 11. Relative positions of Kulite pressure transducer and blades. (From Ref. 5)

Figure 12. Relative positions or Kulite pressure transducers in case wall (From Ref. 5)

C. DATA ACQUISITION

The Kulite pressure transducers were connected to a Hewlett-Packard E1529A Remote Strain Conditioning Unit via an RJ-45 LAN cable. An adjustable power supply would provide the necessary excitation voltage of 5 Volts and was input into the bridge excitation port of the HP E1529A. An Remote Channel Multi-Function DAC Module (HP E1422A), (Ref. 12), controlled and set the HP E1529A to a full bridge configuration, calibration, and self test functions via a program written in HP Vee Pro, (Ref. 13). The HP E1529A provided a wideband amplified output from each strain bridge signal, via a 37-pin connector, to a HP E1433A high-speed digitizer, capable of taking samples up to 196 kSa/sec (Ref. 14). A tachometer signal was also connected to the HP E1433A to provide speed reference data. The tachometer signal came in via standard coax cables and a break-out box was used as an adapter to route these signals into the 27 pin connection of the HP E1433A. The HP E1433A and HP E1422A were addressed through the HP E8404A VXI Mainframe and interfaced to a PC. The data was stored on an Agilent N2216A VXI/SCSI Interface Module, containing two internal 50 Gbyte drives (Ref. 15). The VXI Mainframe was interfaced to a PC, with a 'firewire' interface. DAC

Express, an Agilent program, was used to acquire data. Figure 13 shows the connection of the Kulite transducers to the data acquisition system.

Figure 13. Data Acquisition System (From Ref. 5)

1. DAC Express

The Hewlett-Packard DAC Express was used to monitor the digitized signal in real time (Ref. 16). DAC Express set the sampling rate of the HP E1433A and recorded the digitized data to the Agilent N2216A. DAC Express can analyze up to 16 channels at a time, with the option of recording for any given amount of time. Figure 14 shows an example DAC Express setup screen showing 12 channels in real-time, nine individual Kulites, Kulites 2,7 and 8, the hotwire and the once per rev signal. For the purposes of this experiment, the length of time for the transient pre-stall was .2 seconds, while the two stall cases were 45 seconds. However, for ease of data analysis the stall cases were later reduced to four seconds; two seconds before stall and two seconds after stall. Once

the start button had been pushed and the data recorded, the data had to be exported from the N2216A to the PC as a .csv file. The .csv files were entered into MATLAB, for data processing (Ref. 17).

Figure 14. DAC Express GUI screen

IV. EXPERIMENTAL PROCEDURE

A. KULITE CALIBRATION

Calibration of the Kulite was conducted while the compressor was running, to alleviate any temperature dependence of the Kulite. Four sets of data were taken for the specified throttle and speed setting and each set of data was applied to a reference pressure. The reference pressures were 0, 5, 10 and 15 inches of mercury (0, 2.456, 4.912, 7.368 psig). The applied reference pressure was manually recorded from a Wallace and Tiernan gauge with a mirrored scale graduated in .2 inches of mercury. For the steady state analysis, the DAC Express would record the voltages for .2 seconds, at all four reference pressures. However, for the two stall cases only the reference pressure of 10 psig was recorded into the DAC Express for 45 seconds. Once the data had been recorded as a .csv file it was calibrated and reduced in MATLAB (Ref. 17). The calibration constants calculated in MATLAB from the run closest to stall were used for data analysis and data reduction of the stalled data.

B. COMPRESSOR OPERATION

During testing the Transonic Compressor Rig's rotor was kept at a constant speed and measurements were taken at different throttle settings. By closing the throttle, the mass flow rate was reduced and the rig operating point could be determined by the procedures described by Gannon et al. (Ref. 4). For this experiment the mass flow rate was varied by actuating the throttle (Fig. 15) while the rotor RPM was set at a particular speed.

Figure 15. Electric throttle

Mass flow rate, inlet and exit total temperatures and pressures were measured and recorded. This data was used to calculate total-to-total pressure ratio and isentropic efficiency which was used to determine position on the compressor map. Measurements were taken from open throttle to a throttle position near stall. Measurement and calibration procedures were described in more detail by Gannon et al. (Ref. 3).

C. STEAM-INDUCED STALL RUNS

For the current study the compressor was set at either 70% or 90% speed. The throttle was closed incrementally, pausing only to take the necessary steady state measurements. The process of reducing the mass flow by closing the throttle was done to determine the point at which the rotor would stall before moving on to steam induced stall test.

Once the throttle setting just prior to stall was established, and steady state measurements were taken, the compressor was ingested with steam by the following

procedure. The steam vent solenoid valve and the boiler isolation valve were opened to allow the steam pipe to heat up. Once fully heated, the vent valve was closed and the data trace from the pressure transducer and thermocouple were started. The steam pressure was monitored and once it reached its intended pressure, the isolation valve was closed. At this point a three second countdown to steam ingestion would occur and the Kulite data acquisition system was initiated. Once the end of the countdown had been reached, the fast-acting solenoid valve was opened and the steam was dumped into the plenum of the compressor. After several seconds, the Kulite data acquisition was stopped. If the steam ingestion did not cause a "pop-stall" event, the procedure was repeated at a reduced throttle setting until a "pop-stall" was achieved.

Post processing of the data was conducted with MATLAB (Ref. 17). The procedure for the use of the MATLAB files is presented in Appendix A. Specific M-files that were used with the steady-state data are given in Appendix B and the procedure for the stall tests are presented in Appendix C.

THIS PAGE INTENTIONALLY LEFT BLANK

V. RESULTS AND DISCUSSION

A. STEAM-INDUCED STALL AT 70% SPEED

Given that changes to the honeycomb and pressure ports on the flow rate nozzle were altered the performance characteristics of the Transonic Compressor Rig, transient data using Kulite pressure transducers during steam induced stall at 70% speed needed to be re-established. Figure 16 shows previous data taken on the rotor with a pneumatic temperature and pressure probes, torque, flow, and speed instrumentation, and represents time-averaged information. Figure 16 also shows the single point near stall at 70% speed that was measured prior to steam ingestion (Ref. 18). The green dot was established by Payne and the blue dot demonstrates shift along the stall line due to the changes in the honeycomb and pressure ports (Ref. 8).

Figure 16. Pressure ratio versus mass flow rate with shift in stall line

The transient pressure measured in the steam line was used to calculate the mass flow rate of the ingested steam. Figure 17 shows the pressure change in the steam pipe as well as the temperature change in the inlet of the compressor over time during the steaminduced stall experiment. A pressure of 480 kPa was reached in the steam pipe prior to releasing steam into the compressor. A steam-induced stall of the rotor was observed at 70 percent speed at a mass flow rate of 0.045 kg/s.

Figure 17. Steam pressure and inlet temperature change during steam-induced stall at 70 percent speed

Figure 18 shows the raw-voltage of the Kulite signal going into stall at 70 percent speed. The change in speed of the compressor going into stall is shown in Figure 19.

Figure 18. Raw-voltage Kulite signal going into steam induced stall at 70 percent speed

Figure 19. Change in compressor speed during steam-induced stall

Figure 20 represents a waterfall FFT contour plot of the data taken during stall at 70 percent speed. The stall cell frequency, once per revolution, and the blade-passing frequency, can be seen in this contour plot. The stall cell frequency was approximately 60 percent of rotor speed and there was indication of a precursor to stall at 4.3 seconds. Stall occurred at 4.34 seconds.

Figure 20. Power spectrum contour plot of Kulite data at 70 percent speed through stall

B. PRESSURE CONTOURS 70% SPEED OPEN THROTTLE

Figure 21 shows the pressure contours derived from the nine Kulite transducers at 70% speed.

Figure 21. Pressure contours 70% speed with open throttle

C. STEADY-STATE PRESSURE CONTOURS AT 90% SPEED

The process of reducing the mass flow by closing the throttle while keeping the compressor at a constant speed of 24375 RPM, was done to determine the point at which stall would occur. During this process, the reduction of the mass flow rate resulted in a reduction of axial velocity into the fan and for constant rotational speed, this yielded an increase in incidence. This increase in incidence increased the force on the blades, which yielded an increase in static pressure rise (Ref. 19). Table 3 shows the pertinent measurements while closing the throttle. Run 4 does not include efficiency, or ΔP measurements because this was the run that was closest to stall and steady state data was not able to be taken.

Figures 22-25 are the graphical pressure contours of Table 3. Note the shock wave which moved forward as the mass flow is decreased.

Run	Efficiency (η)	Mass flow	ΔΡ	Pressure ratio
1	86.55	7.56	6.54	1.25
2	89.85	7.23	5.25	1.38
3	83.12	6.24	3.76	1.47
4	-	5.98	-	1.49

Figure 23. Pressure Contours 90% speed and a Pressure Ratio of 1.38 (Peak Efficiency)

Figure 24. Pressure Contours 90% speed and a Pressure Ratio of 1.47

Figure 25. Pressure Contours 90% speed and a Pressure Ratio of 1.49 (closest to stall)

B. TRANSIENT MEASUREMENTS DURING AT 90% SPEED

In order to gather data during a stall event, the compressor was run as close to stall as possible. Once the high speed data acquisition system was activated, the upstream throttle was closed until stall occured. As soon as stall occurred the upstream throttle was reopened and stall stopped as soon as possible to reduce the adverse loading on the compressor. Figure 26 shows the raw-voltage of the Kulite signal going into stall at 90 percent speed.

Figure 26. Raw Kulite data through 90% speed stall

In order to post-process the data the stall speed cell needed to be determined. This speed was acquired through the use of three pressure probes at the same axial location but just upstream of the blades. Figure 27 shows the simultaneous raw voltages at 90% speed.

Figure 27. Simultaneous signal obtained from 3 probes at 90% speed

The stall cell size increased with each revolution but was separated by a region of regular cyclic flow. A full investigation into this phenomenon at different speeds is given by Gannon et. al. (Ref. 20). The change in speed of the compressor going into stall is shown in Figure 28. A fast Fourier transform was also used to create a waterfall power spectrum of the Kulite data as seen in Figure 29 plotted in contour format.

Figure 28. Change in compressor speed during a rotating stall event

Figure 29. Power spectrum contour plot of Kulite data at 90 percent speed at through stall

Figure 29 represents data taken during stall at 90 percent speed. The stall cell frequency, once per revolution, and the blade-passing frequency, can be seen in this contour plot. There was no indication of a stall precursor as measured by the Kulite transducers.

C. 90% SPEED STALL CELL GROWTH

Figure 30 represents the development of the stall cell at 90% speed. The first strip corresponds to the undistributed rotation before the formation of the stall cell. Each subsequent strip corresponds to the stall cell as it passed under the pressure probes on the subsequent rotation. Figure 30 shows the formation of only one stall cell rotating at 60% rotor speed,

Figure 30. 90% speed stall cell growth

Once the stage was stalled it needed to be returned to the original flow conditions. Note that because the speed of the machine was not held at a constant speed during the stall event, the un-stalling of the stage was much less controlled than the entry into stall. As covered by Gannon, when the required pressure ratio across the stage decreases the flow through the rotor, the flow begins to return to its axi-symmetric pattern (Ref. 20).

VI. CONCLUSION

Changes in the honeycomb altered the performance characteristics of the Transonic Compressor Rig. As a result, a steam induced stall at 70 percent speed and new stall line were successfully determined. The transient pressure was measured in the steam line and the mass flow of the steam was established. Kulite pressure transducers recorded the pressures prior to and during steam induced stall. The stall cell induced by the steam rotated at 60 percent of rotor speed with slight precursor for 0.04 seconds.

Performance measurements were carried out at 90 percent speed from open throttle to stall. This data followed previous trends with respect to peak efficiency and total pressure ratio. A graphical analysis of the data was used to better visualize the structure of the flow as well as the stall cell and its growth. The measured stall cell also rotated at 60 percent rotor speed with little or no indication of any precursor.

A steam induced stall at 90 percent speed is planned. With the aid of the graphical techniques presented, insight could be gained into the formation and propagation of the steam induced stall.

THIS PAGE INTENTIONALLY LEFT BLANK

APPENDIX A: PROCEDURE FOR USE OF MATLAB M-FILES

Stall case

Directory that contains all the files:

C:\Bill Levis\Kulite Rotor Only\90%\90%2004 09 14 Rot only 0.00%\Stall

load data 90 is the file which calls all of the others

On line 14 in load data 90 reads:

%Raw data = dlmread('Dx2004 0914 1001 90 stall.csv',',','A187500..M200000'); %

'Dx2004_0914_1001_90_stall.csv' is the csv file will be read and needs to be altered to accommodate a new set of data

A187500..M200000 corresponds to the cells and time of the stall event

The timed can be determined by trial and error or can be determined by using the DAC Express to find the exact time of the stall event. And given that each cell corresponds to .00001 seconds one can determine which cells are at the inception of stall. For example, the exact time that was determined using the DAC Express was 5.861 seconds. Given that the data starts at 3.5 seconds. The difference between the two is subtracted and than divided by .00001.

*Note

Because there is no calibration procedure for the stall case the calibration constants closets to stall will be used in the stall case. Run the steady state programs for the case closest to stall. The calibration constants will be created in:

C:\Bill_Levis\Kulite_Rotor_Only

under the file name "Kulite_calibrate"

for the 90% speed case rename Kulite_calibrate_to Kulite_calibrate_90

and place the newly renamed file into

C:\Bill_Levis\Kulite_Rotor_Only\90%\90%2004_09_14_Rot_only_0.00%\Stall directory

load_data_90 can now be run

*Note

If color scheme isn't working the contour map needs to be reset to within tolerance. This can be accomplished in load data 90 line:

contourf(PR_X,PR_Y,PR_Z,[0.4752:(1.4619-0.4752)/35:1.4619])

steady state

There should be 4 csv files for dictated percent speed as well as mass flow corresponding to the different back pressures. As default they need to be saved in this directory:

C:\Bill Levis\Kulite Rotor Only\90%\90%2004 09 14 Rot only 0.00%\Run11

*Note: this directory can be changed but alterations to the code need to be made

The following directory contains the necessary files to run the steady state calculations:

C:\Bill_Levis\Kulite_Rotor_Only

kulite_rotor_only is the file which calls all the others

In kulite_rotor_only line 12 needs to be changed:

Kulite_constants = 'Kulite_constants_90_PR_1_49'; % 90% speed near stall

Kulite_constants_90_PR_1_49.m dictates which directory will be used

Again unless one wants to alter the code the following directory needs to be used:

C:\Bill_Levis\Kulite_Rotor_Only\90%\90%2004_09_14_Rot_only_0.00%\Run11
