INTRODUCTION

There have been numerous modeling methods developed to predict the dispersion of air pollution. In recent years there have also been several major modeling efforts directed at aircraft operations. An early model was developed by Northern Research and Engineering Corporation (NREC)². This model provided the basis for the GEOMET model³ which has been validated to some extent by measurements at the Washington National Airport⁴. Military operations (aircraft and air-base) differ significantly from civilian operations. For this reason the USAF contracted the Argonne National Laboratory to develop an air quality assessment model (AQAM) for Air Force operations⁵⁻⁹. The latter model was based upon an earlier TRW Model, the Air Quality Display Model (AQDM)¹⁰.

Most of these aircraft related models consist of three major parts, a source inventory model which yields rates and quantities of emitted pollutants, a short term dispersion model and a long term dispersion model. Many of the techniques (and their limitations) which have been used to predict the spreading rate from elevated sources have been discussed by Mathis and Grose¹. Most of the models are solutions to the diffusion equation assuming Gaussian dispersion in both the horizontal and vertical directions^{1,11}. In these cases the plume dimensions are specified by vertical and horizontal standard deviations (σ_y, σ_z) which in turn are functions of the atmospheric stability and the downwind distance or travel time. The models predict average steady state concentrations over some time interval; typically ten minutes or one hour for the short term models. Special provisions are made to account for very low wind speeds and the presence of elevated stable layers (lid height). Plume rise due to thermal buoyancy and vertical momentum and downwash effects are

sometimes used to obtain "effective" emission heights. Most models neglect gravitational settling and chemical reactions within the atmosphere although a few consider the latter effect through a specified half-life. Short term models assume an average wind speed and direction and atmospheric stability class over the dispersion time considered.

Aircraft operations are specified through a landing and take-off operational cycle time-in-mode (LTO). The cycle is defined by the number and type of operational modes required to complete the cycle. The EPA utilizes ten, and the USAF eleven, operational modes to define an LTO cycle¹².

Accuracy of model predictions depends both upon the assumptions employed in the dispersion model and upon the detail and accuracy of the specified emission rates for aircraft, air-base and off air-base (environs) operations. Long-term models appear to agree reasonably well with observations¹⁴. However, none of the short term models for aircraft operations have been validated as quantitatively accurate and it is doubtful that they will ever give a good comparison of concentrations on an hour-by-hour basis^{11,13,14}. The values of σ_y and σ_z are not known accurately (especially in the near-source region)^{11,14}, sources are not continuous, and atmospheric conditions are not steady. However, the models have been shown to be good qualitative tools for assessing the effects of changes in operating procedures and meteorology on atmospheric pollution levels¹⁴. In addition the short term models appear to predict frequency distributions which are in reasonable agreement with observations¹⁴.

Regardless of the accuracy of the model for modeling the airbase operations, modeling of the surrounding environment is very difficult. It is this background level of pollution (which is typically much greater than the

aircraft/air-base generated pollution) that has made it impossible to date to adequately validate any of the short term models. In addition, the cost is high in equipment and manpower to operate adequate sampling stations. A large data base is needed which includes a wide range in meteorological and operational conditions. Nevertheless, validation of the models needs to be done in as complete and well planned manner as is affordable. This is required if the models are to be used with confidence in assessing the effects of aircraft/air-base operations on both the airbase and the surrounding community.

The validation process can concentrate on high or low intensity sampling (instantaneous vs. continuous) or both in some combination. It can be done for "on-base" effects or airbase effects on the local environment. It can consider only ground level concentrations or may include some elevated receptors. Validation can also be done for some of the sub-models within the overall dispersion model. Some of these sub-models are based upon questionable assumptions. For example, what are appropriate values for σ_y , σ_z and plume rise for the aircraft jet exhaust during take-off?

Before validation work is conducted it is necessary to determine the sensitivity of the model predictions to its input parameters (meteorology and operations). The sensitivity results indicate under what conditions the model can be best validated if only limited sampling can be accomplished. In addition, the model can be used to help locate the optimum receptor locations for model validation. The sensitivity of the model (or sub-model) to the input parameters needs to be assessed at a particular receptor location with all sources (aircraft, air-base and environ) present because of the interactions that occur between various sources (i.e. variations in "combined" concentrations of multiple sources at one receptor).

Previous model validation and sensitivity studies¹⁴ (with only point and area sources) have shown that (a) predicted concentrations are very sensitive to the specified stability class and vary more with wind direction than observed, (b) the values of σ_z employed strongly affect the model predictions for high lid heights (2500 m), (c) the models are weak or inapplicable for low wind speeds (< 1.5 m/sec), and (d) the predicted concentrations are strongly dependent upon the lid height under unstable atmosphere conditions.

This investigation was conducted to determine the sensitivity of an air quality assessment model (AQAM) for Naval air operations^{15,16} to specified input for meteorological and operational conditions. The sensitivity study was conducted for operations at NAS, Miramar, California to precede a model validation effort at that facility which is scheduled to begin during the summer of 1978.

AQAM FOR NAVAL AIR OPERATIONS

The Source Inventory and Short Term Dispersion Computer Codes of the AQAM model for Air Force operations⁵⁻⁹ were modified for application to Naval Air Operations^{15,16}. Details of the modifications are presented in references 15 and 16.

The EPA utilizes ten, and the USAF eleven, operational modes to define a LTO cycle. Take-off and landings in these LTO's were restricted to a vertical plane and did not define operational modes which are peculiar to the USN; such as hot refueling, field carrier landing practice (FCLP), Navy touch-and-go (TGO) and approaches made under visual flight rules (VFR). In addition, take-off delays and operations peculiar to rotary wing operations (hover work, pad work, autorotations) were not included in these original models. These operations were incorporated into the AQAM model and resulted in an LTO cycle with 21 operational modes as shown in Table I.

Table II presents the additions made to the input routines of the original AQAM program. The additions are grouped by the data sets specified in AFWL-TR-74-54⁶.

Many of the operations added to the LTO occur at heights greater than 500 feet above ground level (AGL). These may not affect ground level pollutant concentrations near the airbase but contribute to total emissions and to pollutant concentrations at elevated heights.

A plot routine was also incorporated into AQAM so that predicted pollutant distribution patterns could be more readily observed.

MODEL SENSITIVITY STUDY

In order to determine the sensitivity of the model predictions to the input meteorological and operational conditions and to certain model parameters (σ_y , σ_z , etc.) many parameters were independently varied. The imposed variations were not intended to be simulations of actual conditions, since in most cases the variation of one meteorological condition (i.e. wind speed) affects another (i.e. stability level). The independent variations do provide valuable data for model validation.

The sources included in the model for NAS Miramar are presented in Table III. A map showing representative grid locations is shown in Figure 1. The receptor grid employed had a one kilometer spacing.

The nominal conditions and variations employed in the sensitivity study are presented in Table IV. Specific cases which were run are presented in Table V.

RESULTS AND DISCUSSION

General Discussion

The sensitivity of the multiple source model predictions to the parameters presented in Tables IV and V should in general follow the Gaussian behavior for individual point and line sources. However, the behavior at a particular receptor will depend to a large extent on its location relative to the various (and numerous) sources throughout the receptor grid. From a model validation standpoint it is important that hourly average type data be collected at locations where the air-base/aircraft contributions are large compared to all environ (background) concentrations. "Optimum" receptor grids for model validation should be found which have both large air-base/aircraft contributed pollution concentrations and concentrations which are sensitive to meteorological and operational conditions. In addition, at least one (and preferably more) receptor should be located upwind of the airbase to determine background levels of pollution.

In addition to the hourly average data based on continuous sampling, the Air Force validation effort at Williams AFB has pointed out the necessity for characterizing individual sources with short sampling time, non-continuous data.

For point sources, the Gaussian dispersion formula for ground level ($z = 0$) concentrations has been presented by Turner¹¹.

$$\chi(x, y, z=0; H) = \frac{Q}{\pi \sigma_y \sigma_z \bar{U}} \exp \left[-\frac{1}{2} \left(\frac{y}{\sigma_y} \right)^2 \right] \exp \left[-\frac{1}{2} \left(\frac{H}{\sigma_z} \right)^2 \right] \quad (1)$$

where:

χ = concentration, g/m³

Q = uniform emission rate, g/sec

σ_y, σ_z = standard deviations of plume concentration in the horizontal and vertical directions respectively, m

\bar{U} = mean wind speed, m/sec

H = initial plume height, m

For concentrations along the plume centerline ($y = 0$) the first exponential term vanishes and for ground level sources with no plume rise ($H = 0$) the second exponential vanishes.

When vertical diffusion is limited by a stable layer at height h_{lid} the diffusion equation must be modified. Turner¹¹ suggests that when the downwind distance is twice that required for σ_z to become equal to $0.47 h_{lid}$, then the plume can be considered as uniformly distributed in the vertical direction. Then (1) becomes

$$\chi(x, y, z; H) = \frac{Q}{\sqrt{2\pi} \sigma_y h_{lid} \bar{U}} \exp \left[-\frac{1}{2} \left(\frac{y}{\sigma_y} \right)^2 \right] \quad (2)$$

For (infinite) line sources Turner has presented:

$$\chi(x, y, z=0; H) = \frac{2q}{\sin\phi \sqrt{2\pi} \sigma_z \bar{U}} \exp \left[-\frac{1}{2} \left(\frac{H}{\sigma_z} \right)^2 \right] \quad (3)$$

where:

q = source strength per unit distance, g/sec-m

ϕ = angle between line source and wind direction, $45^\circ < \phi < 90^\circ$

Behavior of the short-term model predictions under varying meteorological conditions should in general follow equations (1), (2), or (3) depending upon the receptor location relative to the dominant emission source. At receptors where multiple sources contribute significantly the behavioral trends will not be so readily estimated a priori.

The effects of individual variations in meteorological and dispersion model parameters are discussed below in order to examine the sensitivity of the model predictions. It is not implied that these parameters can be varied independently in actual practice.

Results of the parametric study are presented in Tables VI through XVII and are listed below:

<u>Results presented</u>	<u>Table Number</u>
Maximum receptor locations and concentrations	VI

Effects of specified initial vertical dispersion parameter	
(a) all point sources	XIV
(b) all area sources	XV
(c) all line sources	XVI
Special receptor concentrations	XVII

Receptor Locations for Model Validation

Environ sources were predicted to peak south of the airbase at receptors (11,2), (11,3), and (11,4). (11,2) is near the center of Montgomery Field and (11,4) lies due north at the intersection with Interstate 15.

For a dominant wind from the WNW (292°), nominal background (to the air-base) pollutions levels (at $x = 8.37$, $y = 8.52$) were $140 \mu\text{g}/\text{m}^3$ and $6 \mu\text{g}/\text{m}^3$ of CO and PT respectively (special receptor #1, Table XVII). Maximum background levels reached 582 and $23 \mu\text{g}/\text{m}^3$ for CO and PT respectively for stable conditions (stability class = JSTAB = 5). More stable conditions (increasing JSTAB) decrease σ_y and σ_z and increase concentration levels (equation (1)). Lowering h_{lid} increased concentrations (equation (2)) while increased wind speeds reduced concentrations (equation (1)) as expected.

These background levels are high (except for particulates) compared to the nominal grid receptors employed and imply that model validation would be difficult except near strong aircraft and/or air-base sources. Table XVII presents data at two such special receptors (#8 and #11). Special receptor #8 is located 0.34 km downwind (for a WNW wind) from the hot refueling area and special receptor #11 is located 0.08 km downwind of the take-off end of runway # 1. At these two locations aircraft sources dominate all others, indicating that they would be adequate locations for measurements to validate the model. However, receptor #11 may be too close to the emission source.

Maximum Receptor Concentrations

All of the following discussion (except as noted) assumes a dominant wind from the WNW (292°). As discussed above, maximum contributions from environ sources occurred south of the airbase (at receptors (11,2), (11,3), and (11,4)). In general, the contribution from air-base sources was negligible. At receptors

where air-base sources were the major contributor (downwind of test cells) overall concentration levels were quite low. However, no attempt was made to locate special receptors downwind of the test cells where concentrations may have been significant during cell operation.

Except for the special receptors discussed above, maximum concentrations from aircraft sources normally occurred for CO, HC and PT at receptor (11,8), near the intersection of runway #1 and the emergency runway (#5). NO_x generally peaked further downwind. Stable conditions (JSTAB = 3,4) and low lid height ($h_{lid} = 200m$) shifted the peak concentrations downwind whereas a shift in wind direction of 20° (WD = 272°) moved the peak concentrations upwind. Larger assumed values for aircraft initial line source width also moved the peak concentrations upwind.

Fig. 2 presents typical variations in the aircraft contribution to concentrations for CO and PT in both the wind and cross-wind directions. Figures 3 and 4 present typical concentration profiles for CO and PT from aircraft sources.

Effect of Meteorological Parameters

Lid Height

The effect of variations in h_{lid} are presented in Table VII for stability classes of 1, 4, and 5. Table XVII presents data for three of the special receptors.

In general, environ and aircraft sources behaved in the same manner. Air-base contributions were small and varied more rapidly and less predictably. Stability class did not greatly effect the variation of concentration with h_{lid} , although it greatly affected magnitude. At near source locations (maximum receptor concentrations) variation in h_{lid} had negligible effect on concentrations except for very unstable conditions (JSTAB = 1). For

JSTAB = 1 , concentrations decreased less than linearly with increasing, but small values of h_{lid} (100 - 400m). For large h_{lid} (800 - 1400 m) peak concentrations did not vary with h_{lid} . This behavior is to be expected from equations (1) (large h_{lid}) and (2) (low h_{lid}). Also as expected, away from peak values, concentration decreased approximately linearly with increasing but small values of h_{lid} and varied little for large values of h_{lid} . As h_{lid} was increased from 200 to 400 m conditions, peak receptor locations moved upwind.

Stability Class

Stability class had the single largest effect on the predicted concentrations. As stability increases (JSTAB = 1 \rightarrow 5) , σ_y and σ_z drop and ground level concentrations generally increase (equation (1)). Tables VIII and XVII indicate that concentrations can increase by factors of 3 to 5 for JSTAB increases from 1 to 5. At special receptors increases by as much as a factor of 10 were predicted. For large h_{lid} the effect is more pronounced than for low h_{lid} .

Again, aircraft and environ sources behaved similiary but air-base sources varied unpredictably with increasing stability.

Wind Speed

Increasing wind speed (Tables IX and XVII) decreased concentrations of all sources approximately linearly as expected from equation (1), (2) and (3). More rapid variations occurred when receptors were very close to a strong source (special receptor #11, Table XVII).

Wind Direction

Wind direction (Tables X and XVII) had negligible effect on concentrations from environ sources. As the wind direction was changed from 292° to 272° the wind became nearly parallel to the primary taxi and runway line sources. Peak concentrations from aircraft sources dropped by as much as 20% and downwind receptor concentrations increased by as much as a factor of 3.5.

Ambient Temperature

An ambient temperature change of 10°F (Table XI) as an independent parameter had no effect on predicted concentrations.

Dispersion Model Parameters

Initial Aircraft Line Source Width (Table XII)

This parameter had negligible effect on concentrations from aircraft sources for nominal lid height (800 m) and stability class (1). Effects at special receptors and for other meteorological conditions were not determined.

Aircraft Line Source Emission Height (Table XIII)

This parameter had negligible effect for nominal meteorological conditions except at special receptor #8 (downwind of hot refueling). At this receptor, increasing the aircraft emission height from 4 m to 16 m reduced the predicted concentrations by approximately a factor of 3. Plume rise of jet exhausts (which are neglected in the model) may have a dominant affect on model validation at particular receptors.

Initial Vertical Dispersion Parameters (Tables XIV, XV, XVI, XVII)

Increasing (separately) the initial vertical dispersion parameters for point, area, and line sources by a factor of 1.5 had negligible effect on predicted concentration except at near source special receptors. Even at the latter locations predicted variations were less than 20%.

Aircraft Line Sources Above 150 m Altitude

Eliminating all aircraft line sources above 150 m altitude had insignificant effects upon predicted ground level concentrations for nominal meteorological conditions. For very low lid heights significant effects may occur, but were not investigated. The aircraft sources above 150 m do contribute significantly to the total yearly pollutants emitted by aircraft at NAS, Miramar.

CONCLUSIONS AND RECOMMENDATIONS

Ground level pollution concentrations at NAS, Miramar have been predicted using the modified AQAM model for various meteorological conditions and model parameters. Special receptors locations have been identified which appear to be ideally suited for model validation efforts.

Air-base contributions to the predicted concentrations were very small. Background (environ) source levels for all but particulates are high and will make model validation difficult except at special receptors where aircraft sources dominate (for example, downwind of hot refueling and the take-off end of runway #1). Aircraft particulate sources dominate all other particulate sources throughout the receptor grid.

Plume rise of aircraft jet exhausts during taxi, idle and take-off may significantly affect measured ground level concentrations. Model changes may be required to incorporate this effect.

The NAS, Miramar data incorporated into the modified AQAM model were for the year 1975 and may require updating before comparison with measured data is performed.

TABLE III

Summary of Sources at NAS Miramar

I. Air-Base Sources

15 Point Sources

- 1 training fire
- 5 test cells
- 2 run-up stands
- 1 power plant
- 6 storage tanks

30 Area Sources

- evaporative breathing
- space heating
- off-road vehicles
- civilian vehicles

22 Line Sources

- civilian vehicles

II. Aircraft Sources

0 Point Sources

18 Area Sources

- 6 parking
- 4 refueling
- 1 take-off delay
- 7 pads and hover

173 Lines

- LTO modes

III. Environ Sources

1 Point Source

- off-base test cell

18 Area Sources

- land-use

9 Lines

- roadways

TABLE IV

Model Parameters

	<u>Nominal</u>	<u>Variations</u>
Wind Speed (m/s)	2.57	3.6, 9.27
Wind Direction (cw from north)	292	272, 287
Temperature (°F)	60	70
Turner Stability class	1	2,3,4,5
Lid Height (m)	800	100,200,400,1400
Initial Line Source Width for A/C Taxi and Runway (m)	20	15,30
Initial Vertical Dispersion parameter for A/C taxi and runway (m)	8	12
Average Emission Height for A/C taxi and runway Lines (m)	4	8,16
Initial Vertical Dispersion parameter for all point sources	-	x 1.5
Initial Vertical Dispersion parameter for all area sources	-	x 1.5
Initial Vertical Dispersion parameter for all line sources	-	x 1.5

TABLE XVII

Effects of Meteorological and Model Parameters on
Concentrations ($\mu\text{g}/\text{m}^3$) at Special Receptors

Nominal Conditions: Stability class = 1, $h_{\text{lid}} = 800$ m,
wind direction = 292° , wind speed = 2.57 m/sec, ambient
temperature = 60°F , A/C line source height = 4 m

Receptor #1 (x = 8.37 km , y = 8.52 km) - Background

Aircraft: $\mu \approx 0$, all conditions

Air-base: $\mu \approx 0$, all conditions

Environ:	μ_{co}	μ_{pt}	<u>Conditions</u>
	140	6	nominal
	250	9	$h_{\text{lid}} = 200$ m
	582	23	JSTAB = 5, all h_{lid}
	113	4	WD = 272°
	41	2	WS = 9.27 m/sec

Receptor #8 (x = 10.79 km, y = 8.17 km) 0.34 km downwind of hot
refueling area

Aircraft:	μ_{co}	μ_{pt}	<u>Conditions</u>
	574	280	nominal
	592	292	other h_{lid}
	1304	756	JSTAB = 5, all h_{lid}
	559	270	WD = 272°
	154	75	WS = 9.27 m/sec
	203	119	$Z_{\text{A/C lines}} = 16$ m
	503	248	$1.5 \times \sigma_{z_0}$, all line sources

Air-base: negligible

TABLE XVII, CONT'D

Environ:	60	2	nominal
	201	7	$h_{lid} = 200 \text{ m}$
	40	1	$h_{lid} = 1400 \text{ m}$
	321	10	JSTAB = 5, all h_{lid}
	52	1	WD = 272°
	17	1	WS = 9.27 m/sec
<u>Receptor #11</u>	(x = 12.28 km, y = 8.31 km)		0.08 km downwind of
	take-off end of runway #1		
Aircraft:	μ_{co}	μ_{pt}	<u>Conditions</u>
	3496	2031	nominal
	no significant change		$h_{lid} \leq 400 \text{ m}$
