**Title and Subtitle:** Performance Improvements to the Naval Postgraduate School Turbopropulsion Labs Transonic Axially Splittered Rotor

**Authors:** Michael C. Lehrfeld

**Abstract:** Performance improvement investigations to the Naval Postgraduate School Turbo Propulsion Laboratory’s (NPS TPL) Transonic Axially Splittered Rotor were investigated. Implementation of current NPS TPL design procedure that uses COTS software (MATLAB, SolidWorks, and ANSYS-CFX) for the geometric rendering and analysis was modified and documented. Numerical simulations were conducted and experimental data were collected at the NPS TPL utilizing the transonic compressor rig. This study advanced the understanding of casing tip gap, rotor-stator interaction, stator relative blade placement of a hybrid tandem/splittered design, and performance benefits.

The reduction in rotor tip gap produced higher performance benchmarks as predicted. The addition and analysis of multiple blade rows proved to be straightforward and the design methodology and in house procedure was further optimized. While other studies sought to affect the pressure surface of the lead blade, it was determined that using the trailing blade to influence the high momentum flow over suction surface of the lead blade produced better performance gains. With tip gap closure and the addition of the stator stage, rotor alone performance was improved from experimentally measured peak total-to-total pressure ratio of 1.69 to 1.99 and the peak total-to-total isentropic efficiency from 72 to 77 percent at 100 percent design speed.

**Subject Terms:** Turbomachinery, axial compressor, splittered rotor, hybrid stator

ABSTRACT

Performance improvement investigations to the Naval Postgraduate School Turbo Propulsion Laboratory’s (NPS TPL) Transonic Axially Splittered Rotor were investigated. Implementation of current NPS TPL design procedure that uses commercial-off-the-shelf software (MATLAB, SolidWorks, and ANSYS-CFX) for the geometric rendering and analysis was modified and documented. Numerical simulations were conducted and experimental data were collected at the NPS TPL utilizing the transonic compressor rig. This study advanced the understanding of blade-casing tip gap, rotor-stator interaction, stator relative blade placement of a hybrid tandem/splitted design, and performance benefits.

The reduction in rotor tip gap produced higher performance bench marks as predicted. The addition and analysis of multiple blade rows proved to be straight forward and the design methodology and in house procedure was further optimized. While other studies sought to affect the pressure surface of the lead blade, it was determined that using the trailing blade to influence the high momentum flow over suction surface of the lead blade produced better performance gains. With tip gap closure and the addition of the stator stage, rotor alone performance was improved from experimentally measured peak total-to-total pressure ratio of 1.69 to 1.99 and the peak total-to-total isentropic efficiency from 72 to 77 percent at 100 percent design speed.

ACKNOWLEDGMENTS

Thank you to my advisors Drs Anthony Gannon and Garth Hobson and CDR Scott Drayton. Without your insight and guidance I’d be floundering at the keyboard. Thank you to John Gibson for allowing me to work in your lab.

Above all, thank you Dawn, for all your understanding and support. Without you nothing is worth it.
THIS PAGE INTENTIONALLY LEFT BLANK
I. INTRODUCTION

A. MOTIVATION

Recent studies at the Naval Postgraduate School (NPS) Turbopropulsion Laboratory (TPL) have explored the design and performance of axial compressors with splitter blades. Historical studies have shown high efficiencies and pressure ratios but with limited mass flow operating ranges. Drayton [1] developed an alternative design geometry and produced and tested the transonic axially splittered rotor (TASR). TASR displayed an isentropic efficiency of 72 percent with a total-to-total pressure ratio of 1.7 when tested with a large tip gap of two percent of blade height.

This study sought to advance the understanding of axial compressor rotors with splitter blades through the experimental investigation of blade to case tip gap (TG) distance and its effect on stage efficiency and pressure ratio. Additionally, Drayton’s design tools were modified to produce a simulated stator stage to be paired with the TASR. Smaller form factor engine stages with performance of multiple traditional stages will lead to overall smaller gas turbine engines with no penalty in performance or same form factor with increased performance and less complexity.

B. PREVIOUS WORK

1. Rotor Tip Gap

While the Drayton design was influenced by Wennerstrom [2], [3], Tzuoo [4] and McClumphy [5], the design departed from previous work in the areas of blade geometry, placement, blade number and solidity. At 100 percent speed, Wennerstrom demonstrated total-to-total peaks of 3.47 in pressure ratio and 85 percent in isentropic efficiency. Mass flow rate range was three percent. Figure 1 depicts Wennerstrom’s design with 60 blades, with 30 main blades (MB) and 30 splitter blades (SB). The splitter blades were 50 percent chord of the main blade and all blades had their trailing edges aligned axially. Drayton reduced the number of blades from 60 to 24 with a large departure in blade geometry and relative position, Figure 2. Pressure ratio of 1.69 and efficiency of 74 percent were measured with a mass flow rate range of 7.5 percent. While total-to-total
performance numbers are considerably lower than Wennerstrom’s design, TASR doubles the mass flow rate range. The rotor was tested with large tip gap (TG) clearances to safeguard its integrity during initial testing.

Figure 1.  Wennerstrom’s transonic axial compressor splitted rotor (after [1])

Figure 2.  TASR solid model (after [1])
2. **Transonic Rotor with Stator Incorporation**

   No investigations of the NPS TPL rotor paired with a stator design have been conducted. This study is the first to investigate the current NPS rotor geometry with a hybrid splitted/tandem stator design.

C. **CURRENT STUDY**

   Objectives of this study is to modify existing TASR casing to produce smaller TG, test the resultant geometry in comparison to numerical models and previous TG distances. Design, test, and evaluate a tandem stator stage paired with the TASR.

   - Further develop NPS TPL design tools for the inclusion of additional blade rows
   - Redesign NPS TPL Transonic Compressor Rig (TCR) for a wider range of compressor geometries and improved reliability and survivability
   - Decrease rotor-casing tip gap and characterize performance improvements.
   - Design a hybrid tandem/splitted stator row to accompany the TPL transonic splitted rotor
   - Characterize performance of rotor-stator through numerical methods and incorporate rotor and hybrid stator into TCR
II. HYBRID STATOR DESIGN

A. TPL DESIGN TOOLS

The TASR, and TPL Hybrid Stator (THS) design was accomplished using the method of Drayton [1] with modifications, for completeness a brief description of the unmodified procedure is contained here. The design goals were to maximize total-to-total isentropic efficiency, maximize total-to-total pressure ratio, and achieve an axial flow field at stage outlet.

A MATLAB 2013a script contained the geometric parameters shown in Appendix A, Table 1. These parameters and other scripts were called to create the rotor hub, spinner, casing and blades. This data was then passed to SolidWorks 2012 to produce a model with the specified geometry. Figures 3-5 show graphical representations of the input parameters as they relate to the physical geometry of blades and the location of the blades on the rotor hub. With the hub, casing and blade boundaries defined, MATLAB instructs SolidWorks to create a fluid domain (or gas path) that fills the space between a main and splitter blade passage. The blades are subtracted from the gas path using a Boolean operation, leaving a representation of a wedge of air containing one set of blades bound by rotor hub and casing. The beginning and end of the wedge is an arbitrary distance from the point of the spinner and the trailing edge of the rotor/stator blade. A representative rotor air wedge beginning upstream of the spinner point and ending at the end of the rotor blisk is shown in Figure 6. The air wedge in parasolid format is then sent to ANSYS-CFX 14.0 where a computational fluid dynamics analysis is performed to produce a compressor performance map. In this study, the rotor air wedge was modified to end at the location shown to accommodate the stator, which is further downstream than Drayton[1], who investigated the rotor only case.
Figure 3. Blade input parameters

Figure 4. HardCodeBlade passage input parameters (after [1])
B. MODIFICATIONS TO TPL DESIGN TOOL FOR STATOR DESIGN

Using the rotor geometry as a base line design, a blade location parameter was used to move the stator datum 59.69 mm (2.35 inches) further downstream from the zero line shown previously in Figure 4. This placed the leading edges of the stator blades an acceptable distance from the trailing edge of the TASR and allowed for incorporation of additional hub material to structurally support the blades upon manufacture. The rotor air
wedge was initially cut at an arbitrary distance from the trailing edge of the rotor blades. To add the downstream stator blade row, the rotor air wedge had to be cut at the downstream face of the rotor blisk and the upstream portion saved as a SolidWorks part. The THS air wedge is similarly constructed with the portion of the air wedge upstream of the stator blisk discarded. As both air wedges are built on the same coordinate system, combining the two wedges is accomplished by creating an assembly that mates the common surface automatically. Figure 7 shows a completed rotor and stator air wedge. Upstream and downstream air wedge cuts were arbitrary, but attention was paid to having the free stream perpendicular to the inlet face, an adequate upstream distance to from rotor to limit shock smearing, outlet flow that is representative of the resultant vector field after interaction with the stator stage and an undistorted outlet pressure field. Increased computational time associated with larger air wedge volumes was also considered.

Figure 7. Combined TASR/THS air wedge
The combined air wedge was imported into ANSYS CFX where periodic and interface surfaces were defined. The CFD project was defined as a rotating frame rotor domain and stationary frame stator domain with a stage interface between the two. Fluid parameters, rotational velocity, and outlet back pressure were passed through a MATLAB script interface to ANSYS Workbench. Speed line generation was accomplished through the automation process described in Drayton [1] and through manual individual point investigations.

C. TPL HYBRID STATOR BLADE GEOMETRY DESIGN

The initial blade design involved changing blade parameters from the TASR transonic configuration to shapes more suited to subsonic Mach numbers. The upstream blade on the stator blisk will be referred to as the lead blade (LB) while the tandem/splitter blade will be the trailing blade (TB). Blade chords were 50.8 mm (2 in) and 63.5 mm (2.5 in) for the LB and TB respectively with a trailing edge/leading edge overlap near 12.7 mm (0.5 in).

The geometry design process began with calculating the rotor exit plane average flow angles and manipulating the blade stagger to match LB leading edge angle with the incident flow. Visualization of the vector flow field at various blade heights enabled selection of leading edge stagger angle. LB stagger angles were changed to manipulate blade camber with the goal of turning the flow while minimizing flow separation on the suction side. This evaluation was accomplished through the ANSYS CFX programs resident post processing flow visualization features. Visual inspections of flow field vector plots at five passage heights from hub to casing allowed the tailoring of blade camber to manage flow separation. Representative examples of flow field vector results are show in Figure 8. Once an initial geometry was obtained, the specified backpressure (0.70 to 0.80 atm) was increased to find the point where the mass flow (4.27 to 4.32 kg/s) matched the maximum efficiency points of the rotor at 100 percent operating speed with no tip gap. With this backpressure, THS geometry iterations continued until a maximum isentropic efficiency of 77.5 percent was achieved.
Figure 8. Flow Visualization at different radial height
1. Effects of Blade Offset

The majority of blade design efforts involved manipulating the camber of the LB and TB. The blade offset parameter defined in Appendix A Table 1, was initially used to ensure the blades did not physically overlap when drawn on the stator hub and had some moderate separation between LB suction surface and the TB pressure surface. While an arbitrary distance was adequate for initial design, subsequent iterations showed the value of varying blade offset to produce a local “aerodynamic throat” that would reenergize the flow and produce a delay in flow separation. Figure 9 shows the relative effects of various offset inputs. The final design offset was 0.8 of the passage width, with the hub at 0.85 and tip at 0.87. Of note, while -0.25 and 0.75 offset should be identical, care must be taken when using the algorithm used to draw the air wedge. It can produce incorrect shapes for some input parameters. Choosing the alternate input will resolve any geometry issues.
Figure 9. Stator blade offset geometries

2. **Bowed Blade Ends**

Flow separation and vortex generation in the blade-casing and blade-hub interface regions is the last hurdle in producing a well behaved and efficient flow field at the target mass flow. As discussed by Vavra [6], Breugelmanns et al. [7], and Sasaki and Breugelmanns [8], wall boundary layer buildup and blade corner region interaction can be controlled with dihedral or lean angle. Bowing the blade at both casing and hub can reduce the losses due to suction surface flow separation. Figure 10 shows the wakes of the stator blades with and without blade bowing for the same back pressure.
Figure 10. Stator blade wakes showing the effect of bowing
III. EXPERIMENTAL FACILITY AND PROCEDURES

The rotor was tested in the TCR facility at the NPS TPL. The TCR layout was as designed by Dr. M. H. Vavra, and as described by McNab [9] with the exception of those modifications described in Drayton [1].

This chapter describes the modifications required to install the redesigned rotor casing, the stator, the experimental procedures followed for data collection, and the data acquisition and reduction methods.

A. ROTOR ONLY TIP GAP MODIFICATIONS

1. Transonic Compressor Rig

A detailed description of the compressor rig installation is included in Drayton [1]. The TPL transonic compressor rig (TCR), Figure 11, includes a casing ring, AS2 as depicted, which is designed to contain blades in the event of failure, provide instrumentation portals, and provides a mounting surface for abradable tip gap sealing material in the form of a radially wider inner channel corresponding to the rotor blade tip path. As rotor speed increases, the blades will radially elongate and contact the abradable material. The blade tips behave like a cutting edge and machine the abradable surface until a minimal TG is achieved. This behavior would be present at ever increasing rotor speeds thus maintaining a small TG on initial testing. Subsequent testing would obtain optimal (minimal) tip gap distance only at full operating speed, which is typical of actual engine design and operation.
2. Initial Rig Mounting Design and Changes

Initial design of the rotor and TCR interface proved to be inadequate. To attach the rotor to the TCR, the rotor downstream face was machined with a raised lip surrounding the mounting bolt holes. The interface is shown in Figure 12 with overall components shown in Figure 13. Initial design and manufacture specified a relatively loose fit, with a 0.0381 mm (0.0015 in) clearance between rotor mounting race and mounting flange. This loose fit coupled with low, but within specification, mounting bolt torque produced a catastrophic failure. At operating speeds, the loose fitting flange caused mounting bolts to stretch that increased rotor and shaft separation, which increased vibration. This increased vibration allowed blade tips to impact the rotor casing and remove large sections of the abrasion strip, which then fouled the passage and precipitated the failure of the rotor blades.
These failure investigations lead to an increase in flange diameter for an interference fit as part of the redesign of TCR shaft mounting. The interference fit can be seen in figure 12. The rotor shaft was assembled with mounting dowel pins and the shaft mounting bolts were torqued to new specification, Appendix B. Taking advantage of aluminum’s higher coefficient of expansion, the aluminum rotor was heated to expand the mounting race diameter then placed on the steel mounting flange and aligned. Rotor mounting bolts were inserted and torqued to new specification while the rotor continued to cool. This ensured a tight and most importantly a concentric fit. Flange drawings may be found in Appendix C.
3. Current Modifications

With the mounting flange-rotor interface vibration problem addressed, the rotor casing ring, AS2, was redesigned to allow for more ease in varying tip gap and casing treatments. The region that contains the abradable surface was increased to provide greater flexibility in rotor blade length and geometry. Drawings of this design are contained in Appendix D.

Additionally, the Dow Corning one part silicone rubber abradable material chosen for initial rotor experimentation was replaced. Initial testing with this material installed in the casing ring yielded catastrophic results as abrasion characteristics were not predictable. The Dow Corning compound was retained but machined to increase TG according to Drayton’s [1] description. This increased tip gap allowed initial collection of performance data on the remaining TASR. With unsatisfactory characteristics and performance suffering from the increased TG, West Systems 105 epoxy resin, 209 extra slow hardener, and 407 low density microballoon filler or 410 microlight filler replaced
the Dow Corning product, Figures 14 and 15. The West System product demonstrated predictable and benign fracture and abrasion characteristics. Test pours were prepared using a 5/1 ratio of epoxy to hardener with the addition of filler to desired consistency. The 410 microlight filler (cream color) was chosen over the 407 low density filler (maroon color), Figure 15. The 410 filler is constructed with smaller particles and abrades in a manner akin to sanding, while the 407 filler produced larger particles and tended to fracture in a less desirable fashion.

Figure 14. West System epoxy and hardener
Figure 15. West System filler additives

The initial TG will be 0.711 mm (0.028 in) cold and 0.355 mm (0.014 in) at 27000 rpm or 100 percent maximum operating speed.

B. TRANSONIC COMPRESSOR RIG AND ROTOR INSTALLATION

1. Compressor Installation and Instrumentation

The rotor was installed according to Drayton [1], with modifications to the abradable section of the casing and mounting hardware as described previously.

2. Measurement Devices

Stagnation temperature and stagnation pressure probes collected steady-state measurements in the flow field. Unsteady measurements were collected by static pressure transducers installed in the casing. The steady-state probes used were of the same types as described by McNab [9], 1.59 mm (1/16 in) “miniature head” Kiel probes and 3.18 mm (1/8 in) “Standard Head” combination Kiel/thermocouple probes. A
through description of the Kulite instrumentation can be found in Londoño [10]. The characterization of transient data was not part of this study.

3. **Instrument Placement**

Instrument placement was as described by Drayton [1]. Inlet conditions were measured at the AS1 section, Figure 11, with two Kiel/thermocouple and two static pressure probes. Outlet data was gathered at the AS3 station using nine Kiel/thermocouple probes, 11 Kiel pressure probes, two static pressure ports in the rotor casing and four static pressure ports in the TCR hub. Hub and casing temperature were also collected.

The rotor segment, AS2, housed eight Kulite Miniature IS Pressure Transducers in a 15 degree stagger about the casing radius at increasing axial distance from the upstream face as depicted by the ports in Figure 16. In addition to the eight pressure transducers, 16 static ports were included in a similar stagger-axial shift arrangement.

![Figure 16. Kulite and static port arrangement](image-url)
C. FINAL STATOR DESIGN

The original TCR design allows for modification in an axially modular fashion. The stator stage was rendered as a complete blisk in SolidWorks and then modified for incorporation into the TCR. The blisk was split into two rings as depicted in figure 17. The forward two-thirds of the lead blade is fixed to the upstream ring with the remaining portion of the blade overhanging the trailing blade ring. The trailing blade is wholly supported by the trailing ring. This two ring arrangement allows for the “clocking”, as in Figure 9, of the stator to investigate the relative performance effects of lead-trail blade offset. Once the separate rings are defined, the inner portions of the rings are modified to fit on the TCR stator support structures.

Figure 18 displays the stator support structure, a non-rotating structure within the TCR that supports the addition of downstream stator assemblies. Also shown are “blank” rings that would be mounted downstream of a rotor if a stator was not included in the current testing phase. These blank rings were remanufactured, including the hybrid stator stage and allow for the trail ring to remain fixed in relation to the rig while the lead ring can be mounted at different offset angles. The lead ring is then fixed in position and the remaining sections of the TCR are mounted and the rig is prepared for operation Figure 19. Stator drawing can be found in Appendix E.
Figure 17. Two ring arrangement of hybrid stator with rotor and spinner
Figure 18. Stator Support Structure and “Blank” Stator Rings
D. EXPERIMENTAL PROCEDURE

TCR configuration and operation are described by Grossman [11] but for completeness will be summarized. The test article was powered by two opposed rotor, single stage air-operated drive turbines mounted on a common shaft as shown in Figure 20. These turbines received air from a 12-stage Allis-Chalmers axial compressor capable of providing 2.2 kg/sec mass flow rate with a maximum of 2 atmospheres gage pressure. The test compressor was connected to the drive turbines via the redesigned shaft discussed previously. An air-operated balance piston was located between the compressor shaft and the test compressor to counteract the axial forces exerted during operation and reduce bearing stresses. Compressor speed was controlled via an electronically actuated butterfly valve that was used to throttle the air supply to the drive
turbines. Airflow to the rig was controlled using an electromechanical actuated rotating plate throttling valve and settling chamber. Mass flow rate through the test article was measured by a flow nozzle positioned downstream of the settling chamber.

![TCR configuration after Drayton[1]](image)

Figure 20. TCR configuration after Drayton[1]

Every experimental session began with the start and warm-up of the Allis-Chalmers compressor, introducing air to the balance piston, and initiation of lubrication oil to the bearings via an air driven oil mist system. A pre-test checklist is provided in McNab [9].

Each experimental run produced one speed line. Testing began by throttling the drive turbine supply air to produce a corrected rotor speed that accounted for daily atmospheric conditions. The correction ensures that the rotor runs at the correct tip Mach number. Acceptable corrected speed was within a fraction of one percent of the desired speed. Data collection began with the upstream electric throttle valve in the open position. The valve was closed in varying increments to reduce the air mass flow through the TCR. Throttling increments were varied to reflect the operating regime. Beginning with large steps, the incremental steps decreased to the finest changes possible with the installed hardware as the rotor approached predicted stall conditions. At each throttle position, data measurements were recorded and cross-checked with the CFD-derived performance maps.
E. DATA COLLECTION AND PROCESSING

Steady-state data was collected using the existing TPL data collection system. An HPVEE data acquisition program developed by Gannon [12] and described by McNab [9] measured the TCR steady-state pressures and temperatures. For completeness, a brief description is given. The HPVEE software was installed on a PC that controls a HP Mainframe, which recorded measurements from temperature, pressure and rotational speed instrumentation. Pressure probe monitoring is achieved through three ScaniValve pressure bricks. The HPVEE program calculated mass averaged stagnation pressure, temperature, and isentropic efficiency through mass averaging the temperature and pressure data, Hobson et al [13]. Four data points are collected for each operating point at approximately two-second intervals.

The unsteady data was collected from the Kulite Miniature IS Pressure Transducers located in the rotor segment (AS2) using a DAC Express data acquisition system described by Londoño [10]. All probes were calibrated before each data collection run using 0.2 second samples for successive known backpressures applied to the backside of the probe. During testing, 20 second samples at a speed of 196.608 KHz were recorded on the system’s mainframes for different flow and operating conditions resulting in over a half a million data sample points. Data files were saved in a comma delimited form (*.csv) for Microsoft Excel and processing in MATLAB. Code developed by Londoño [10] was used to reduce the data. Each rotor blade passage was divided equally using 100 points. Blade passage mean pressures were transformed into a pressure distribution map by taking all the Kulite pressure signals at each of the points across the blade passage to produce the smooth mean. The final contour plot was formed by sequentially joining and interpolating the pressure averages for each Kulite data set Gannon [12], which matches experimental data, Figures 21 and 22.

IV. RESULTS

A. ROTOR TIP GAP REDUCTION

Drayton [1] conducted tip gap studies at various design speeds and tip gap distances. As previously discussed, problems with the rotor dynamics and abradable material led to investigations with less than optimal tip gap distances. Numerical investigation were conducted with cold shapes and calculated hot tip gap distances. Blades are calculated to grow in length 0.36 mm (0.014 in) at 100 percent (27,000 rpm) design speed due to dynamic forces.

Figures 23 and 24 show numerical and experimental data for 0.254 mm (0.010 in) and 0.914 mm (0.036 in) tip gap respectively.

Figure 23. Rotor pressure ratio versus mass flow (after [1])
Rotor performance at the large experimental tip gap is well below that of the calculated 0.254 mm (0.010 in) design goals. Additional experimental investigations at 60 percent speed showed that performance from a 0.914 mm (0.036 in) gap was considerably improved when tip gap distance was lowered, Figure 25. The maximum pressure ratio increased to 1.28 from 1.23 and the mass flow rate range increased from 23 percent to 25 percent.

Figure 24. Rotor efficiency versus mass flow (after [1])

Figure 25. Experimental pressure ratio versus mass flow for decreasing tip gap (after [1])
Experimental and numerical power absorbed by the rotor is shown in Figure 26.

### B. ROTOR-STATOR PAIR

Baseline rotor-stator performance is shown in Figure 27. Maximum predicted performance figures are 1.97 (76.7 percent) pressure ratio and 77.5 percent (PR=1.94) efficiency. The stage was evaluated with no tip gap over the rotor and at 70 percent, 80 percent, 90 percent and 100 percent operational speeds, as shown in Figure 28. The pressure ratio and efficiency curves both display like characteristics and the same trends as the rotor only performance map with a slight loss in peak efficiency, Figure 29, and a slight gain (+0.05) peak pressure ratio and predicted mass flow rate range, 8.4 percent versus 5.3 percent.
Figure 27. Baseline rotor-stator pressure ratio (left axis) and efficiency (right axis)

Figure 28. Pressure ratio at various operating speeds
The computed power map for the rotor and stator is shown in Figure 30. For nearly the same mass flow rates, the stage displays slightly lower numerically derived power absorbed than the rotor only configuration at 331 kW vs 339 kW as expected due to the lower computed stage efficiency.

Figure 29.  Efficiency at various operating speeds

Figure 30.  Power at various operating speeds
Additionally, a study to understand the effects of varying the offset between blades was performed. With the baseline stator design offset distance as the control location, air wedges were created by perturbing the trailing blade some distance toward and away from the leading blade. Figure 31 displays the perturbation nomenclature as it relates to the stator. Perturbations from 15 percent of the original distance to 25 percent were conducted.

![Figure 31. Offset perturbation](image)

Though the peak data for positive perturbation in Figure 32 not as behaved as the baseline data, a trend can be observed. For an increased distance between the stator lead and trailing blade there is increased pressure ratio over the baseline design. Unfortunately, the efficiency map, Figure 33, shows that all the perturbed geometries displayed efficiencies less than the baseline design. This is likely due to the fact that the baseline geometry was designed for the baseline offset and not intended to operate at peak performance in off design offset distances.
The negative perturbation pressure ratio and efficiency results are shown in Figures 34 and 35. Unlike the positive perturbation investigations, efficiency increases for a lower pressure ratio as compared to the baseline geometry.
Again, opposite the positive perturbation, which displayed high peak and shallow decay as mass flow decreased, the peaks for negative perturbation peak and fall off quite sharply. Of note is the behavior of the “close” geometries, -20 percent and -25 percent, that stall at much lower mass low rates due decreased distance between lead blade suction surface and the trail blade pressure surface.
V. CONCLUSIONS AND RECOMMENDATIONS

A. CONCLUSIONS

Objectives for this study were to design a tandem stator for inclusion behind an advanced transonic splittered rotor. Redesign and modify the TCR to increase reliability, survivability and flexibility. Modify design tools for additional blade rows and design manufacture and test the blade rows with the TASR. In the pursuit of these goals the following were realized.

- The successful modification of NPS TPL design tools for design of stator rows revealed the flexibility of this program implementation. Additionally, unforeseen program features were revealed in the exercising of the design tools beyond their original scope. This “stress testing” has provided invaluable insight into the design process and enabled the TPL to further modify the tools to increase automation in the iterative design process.

- The design and analysis of the hybrid stator advanced the understanding of a previously unexplored geometry configuration. The inclusion of the hybrid stator completes the splittered rotor stage and demonstrated the performance gains associated with these novel designs. The investigation and inclusion of offset and blade bowing in the stator design increased stator design knowledge and will allow increased performance when further modified for follow on geometries. The two ring configuration of the stator will allow for extensive investigations that will enable an increase in knowledge of the effects of relative blade offset on stator and overall stage performance.

- The redesign of TCR rotor interface and casing will enable the NPS TPL to test a larger range of compressor geometries. The failure analysis process allowed for greater understanding specific dynamics associated
with the transonic compressor rig. This increased understanding and lessons learned will enable success in future testing at all NPS laboratories.

- The decreased tip gap and new abrasion material should increase the rotor only performance the NPS Transonic Axially Splittered Rotor. The performance increases predicted by the more operationally representative tip gap distances promise to increase TASR performance to new state of the art levels. The additional understanding of splitted rotor characteristics will inform further designs to culminate into operational implementation.

B. RECOMMENDATIONS

Follow on studies should use this work as a base and expand on it as follows:

- Develop an experimental performance map of rotor only configurations with decreased tip gap using the redesigned rotor casing and the new abradable material chosen above. Compare this map to the numerical models and validate the performance improvements predicted.

- Develop an experimental performance map of the rotor-stator configuration, with decreased rotor tip gap, using the hybrid stator developed here. Compare this map to the numerical models and validate the performance improvements predicted.
