19. ABSTRACT (continue on reverse if necessary and identify by block number)
The intent of this study is to adapt a general numerical model of fires within an enclosure to a specific experimental test facility. The test facility is operated at the Naval Air Warfare Center, China Lake California. The research facility is in the process of studying missile fuel fires in a surface ship combatant setting. The numerical method employed is capable of generating temperature, velocity, pressure, and density fields for a three dimensional rectangular enclosure. This study is considered preliminary in that much of it concerns the treatment of various difficulties encountered in trying to model a fire with a solid rocket propellant energy release rate using the given computer code. The specific objectives of this thesis are to subject the model to a very high heat input rate and derive results for both a closed and an open compartment. To analyze the open compartment it was necessary to modify the code to incorporate a vent in one of the enclosure walls. A National Center for Atmospheric Research graphics program is used to present isotherm and velocity distribution results.
Approved for public release; distribution is unlimited.

NUMERICAL FIELD MODEL SIMULATION
of
FULL SCALE FIRE TESTS
IN A CLOSED AND AN OPEN COMPARTMENT

I. INTRODUCTION

A. BACKGROUND

The study of fire propagation through computer modeling has been the subject of ongoing research at the Naval Postgraduate School (NPGS). There are numerous factors that support the need for this type of research. Some of the more important among them are:

- reduce the need for full scale fire testing
- provide a means for initial analysis of a given scenario so that the actual experiment may be more effectively conducted
- serve to indicate areas within the test compartment that monitoring equipment would be better placed.
- provide for a better understanding of fire propagation and consequently improve firefighting techniques
- allow for a quicker appraisal of a given fire scenario

Although considerable progress has been achieved in this effort, there are clearly good reasons to expand it. It is to this end that this work is undertaken.

The present objective of this research is to develop a numerical procedure to model a fire research test facility operated at the Naval Air Warfare Center, China Lake, California. This research facility is presently conducting tests involving the combustion of missile fuels within a compartment. The facility is designed to mimic the layout and
construction of a group of surface ship compartments. The research is motivated by the experiences of shipboard personnel during the Falkland Islands conflict and the Persian Gulf USS Stark incident. Missile fuel fires almost immediately ignited all materials within a compartment causing nearly instantaneous flashover. The facility is the first to employ an empirical study to ascertain the hazards associated with missile propellant combustion in a vented shipboard compartment. Eventually the empirical data recorded at the facility will serve to validate the numerical analysis.

The NPGS effort to model the China Lake facility began with a general numerical procedure designed to model fires within a closed rectangular enclosure. The basic numerical model was developed by H.Q. Yang and K.T. Yang of the University of Notre Dame, Department of Aerospace and Mechanical Engineering. It is entitled "Three Dimensional Numerical Simulation of a Fire Spread Inside a Building" and is provided in Appendix B. The code provided by Professor K.T. Yang was rearranged during a prior thesis but this rearrangement was one of appearance and not of substance. Thus this basic numerical method served as the starting point for the analysis presented in this thesis.

B. OBJECTIVES

The fundamental objective of this thesis is to provide a preliminary assessment of the given numerical procedure's
capability in providing solutions for temperature, velocity, pressure and density fields given an extremely potent heat source. No output had previously been generated from this particular numerical method for a heat source characteristic of a solid rocket fuel. Emphasis is placed on the procedure’s performance given this type of source and not on the modeling of the source itself. In addition an attempt is made to incorporate provisions for a hole in one of the enclosure walls opening the compartment to the ambient air.

C. PREVIOUS WORK

The program listed in appendix B is a complex compilation of ideas and methods that have developed over a number of years. A variety of sources had to be referred to in order to apply the program to the given problem and analyze the results. A summary of the material (aside from prior thesis work at NPGS) that was found to be helpful is provided here.

Among the most useful references was the book by Patankar [Ref. 1] which served to provide an overall understanding of the basic solution procedure. Doria et. al. [Refs. 2,3] provides background and the specific derivation of equations that were used in a program written at the University of Notre Dame that was a forerunner to the code used in this thesis. The material written by Yang et. al. [Refs. 4-9] and Chan et. al. [Ref. 10] provides a broad background of information concerning both laminar and turbulent flow in various types of
compartments. These articles directly address some of the methods applied in the program of appendix B.

Models and procedures which merit considerable discussion in this thesis are a global pressure correction routine, stability criteria, and the application of boundary conditions. The global pressure correction routine is discussed in some detail by Nicollette et. al. [Ref. 11]. Leonard [Ref. 12] has written numerous articles concerning the accuracy and stability of the primary finite differencing technique used in this program. Lin et. al. [Ref. 13] provides specific information concerning boundary conditions for an open channel, unsteady flow type problem and served as an example of that which is considered herein.

An indispensable source in this analysis was the information compiled by Minkowycz et. al. [Ref. 14] from numerous authors concerning numerical methods in heat transfer. Information derived from Greenspan [Ref. 15] and Smith [Ref. 16] was helpful in the application of boundary conditions and the analysis of the general properties of numerical methods. Schlichting [Ref. 17] was a good reference source for the underlying theory concerning fluid motion and governing equations. The radiation heat transfer model’s theoretical basis is explained in books such as the one by Sparrow and Cess [Ref. 18]. The Naval Air Warfare Center, China Lake, CA [Ref. 19] provided information concerning the
test facility layout, compartment dimensions and the general nature of the tests being conducted there.

D. PRIOR NPGS THESIS WORK

Other useful sources of information utilized in analyzing the numerical model provided in appendix B, are prior theses, [Refs. 20-24], written at the Naval Postgraduate School. Most of this work concerns the modeling of the FIRE-1 test facility, at the Naval Research Laboratory which is designed to provide empirical data for fires in a cylindrical compartment. It was developed to simulate submarine compartment fires. Nies [Ref. 20] provides an in depth description of the basic three dimensional numerical model for fire propagation in a closed enclosure. Finite difference equations, turbulence models, radiation models, and conduction models are developed based on a Cartesian coordinate system. Most of the derivations discussed by Nies are directly applicable to the model provided in appendix B. Raycraft [Ref. 21] applied equations based on spherical and cylindrical coordinate systems to more accurately model the FIRE-1 test facility. A more detailed formulation of the radiation model is also provided. Houck [Ref. 22] used the spherical and cylindrically based geometry of the Raycraft formulation and provided an internal ventilation model. McCarthy [Ref. 23] applied the existing computer code to the FIRE-1 test facility
and used CA-DISPLA Graphics to present data generated by the program.

Work on the modeling of the China Lake test facility was begun by Thorkildsen [Ref. 24]. Some preliminary runs of the program were accomplished and a NCAR Graphics program was developed to analyze the isotherm and velocity profiles generated by the numerical model.

The major difference between the analysis conducted in this thesis from previous work is that the data presented in the previous theses are for a comparatively small fire. The velocity, pressure, density, and temperature gradients were not nearly of the magnitude generated by the type of fire being studied at the China Lake facility. In addition, no analysis was previously accomplished for an open compartment.

E. PREVIEW OF SUBSEQUENT CHAPTERS

Section B of Chapter I provides the layout of the China Lake facility along with some information of the instrumentation available there. Chapter II presents information related to the output of results by the program. It is intended to provide a basis for discussion of these results. It was necessary to address the numerical properties of the main finite difference scheme employed, the conduction model, boundary conditions, and the global pressure correction routine. An explanation of the modifications made to generate the enclosure opening in the program are also provided in
Chapter II. The third chapter concerns the analysis of data generated by the numerical scheme. NCAR Graphics is used extensively to aid in analyzing the data. Chapter IV is a summary of the research conducted and provides some conclusions and recommendations. Appendix A provides a general program flow chart.

F. CHINA LAKE FACILITY DESCRIPTION

An isometric and plan view of the ship compartment simulator at the Naval Weapon Center (NWC), China Lake is given in figures 1.1 and 1.2 respectively. The facility consists of a main compartment (20ft by 20ft by 10ft high), a compartment (15ft by 15ft by 10ft high) adjacent to the main compartment and a compartment (15ft by 15ft by 10ft high) mounted above the main compartment. All compartments are constructed with 3/8 inch thick steel bulkheads and 1/2 inch thick steel decks. The bulkheads are structurally reinforced with 5 inch I-beams and the deck plating is reinforced with 12 inch I-beams. There are no partitions within the compartments.

Prior to a test run, a ventilation opening of a specific size is incorporated into the wall opposite that of the fire location in the main chamber in accordance with the test scenario. The vent is intended to simulate a missile impact hole in the hull. The fuel pan is placed on the south side of the main chamber enclosure approximately four feet from the east wall. Wooden cribs of various sizes are placed in the
compartment when called for by the test scenario to simulate class 'A' fire materials.

Instrumentation is provided to measure fire compartment gas temperatures, temperatures of escaping gases, air temperatures in the adjacent and overhead compartments and total heat flux at various locations. The bulk compartment pressure can also be measured in the main chamber's northeast corner. Portable thermocouple trees can be installed at any desired location. They extend from 1/2 foot off the deck to 1/2 foot from the compartment overhead.

The tests are run with various amounts of solid rocket propellant in a fuel pan and range from 25 to 200 lbs. The combustion rate for each test was determined by the length of time that it took for the propellant to completely dissipate. From the data made available to the Naval Postgraduate School it ranged from 0.9 to 4.5 lbm/s. Following discussions with test facility personnel, a heat of combustion of 2600 BTU/lbm was estimated for the fuel.

Figure 1.2 Plan view of fire test chamber
II. NUMERICAL MODEL

A. GENERAL

The numerical method used in this analysis incorporates different models for the transport of mass, momentum, and temperature which are linked in a sequential order to develop temperature, velocity, pressure, and density fields for a given heat source. The model for the compartment interior (area within the enclosure walls) uses three dimensional, primitive variable, finite difference methods to calculate velocity, temperature, and pressure fields. The perfect gas law equation of state serves to calculate the density field. It is also incorporated into conservation of mass equations to provide a global pressure correction which assists in solving for the true pressure field in the compartment. The model incorporates strong buoyancy, turbulence and compressibility effects. Provision is made for the placement of solids within the compartment. Finally, a tridiagonal matrix algorithm (TDMA) is used to solve the equations generated by the finite differencing method.

A one dimensional conduction model is provided for heat transfer calculations through the enclosure walls. Enclosure walls of different thermodynamic properties may be input separately into the program.
The heat source may be modeled by any appropriate algorithm and distributed into any portion of the compartment desired. At present provision is made for only a uniform distribution of the source into the control volumes chosen for its location. A radiative heat transfer model quantifies radiative heat transfer from the heat source to the enclosure walls and solids located in the compartment interior. An important feature of the program is that it allows the use of a nonuniform grid.

A detailed development of the basic numerical method in cartesian coordinates is provided by Nies [Ref. 20]. However, the finite differencing technique described by Nies for the space within the enclosure walls is the UPWIND scheme whereas the program used in this analysis utilizes the QUICK (quadratic upwind interpolation for convective kinematics) method which was developed by Leonard [Ref. 12]. The derivation of the finite difference equations for a general coordinate system using the QUICK method is given by Raycraft [Ref. 21] and is directly applicable to this particular aspect of the program. In addition, the conduction model described by Nies is not the conduction model used in this program.

The use of the general numerical method described by Nies and Raycraft to generate results for a very high energy heat source and the incorporation of a vent opening in one of the enclosure walls poses several difficulties. In section B of this chapter the model of the compartment interior is
addressed with emphasis on the numerical properties of the
QUICK scheme. Because problems are encountered in using the
program to generate results for large magnitude fires, it is
necessary to establish some idea of the factors affecting grid
spacing and time steps. Section C addresses the specific
conduction model used in this program. This model appears to
have a significant impact on the results presented in Chapter
III. Sections D and E discuss boundary conditions and the
global pressure correction routine which are major
considerations in modifying the program to incorporate the
vent opening.

B. MODEL OF THE COMPARTMENT INTERIOR

The governing equations for a three dimensional buoyant
flow are well known and are given by Schlichting [Ref. 17].
The equations are reduced to dimensionless form by utilizing
the following definitions:

\[ x_i = \frac{\tilde{x}_i}{H}, \quad u_i = \frac{\tilde{u}_i}{u_R}, \quad p = \frac{\tilde{p}}{\rho_R} u_R^2 \]

\[ T = \frac{\tilde{T}}{T_R}, \quad t = \frac{\tilde{t} u_R}{H}, \quad g_i = \frac{\tilde{g}_i H}{u_R^2} \]

\[ \rho = \frac{\tilde{\rho}}{\rho_R}, \quad C_{pm} = \frac{\tilde{C}_{pm}}{C_{pR}}, \quad \mu = \frac{\tilde{\mu}}{\rho_R u_R H} \]

\[ k = \frac{\tilde{k}}{\rho_R C_{pR} u_R H} \]

where the quantities denoted with the tilde symbol are
and i=1,2,3. Thus \( \mathbf{x}_i \) denotes the cartesian coordinates \( x,y,z \) and \( H \) is the height of the compartment. \( \bar{t} \) is dimensional time, \( \bar{g}_i \) is the component of the gravitational acceleration in the \( i \) direction, \( \bar{u}_i \) the velocity vector, \( \bar{T} \) the temperature, \( \bar{p} \) the static pressure, \( \bar{\rho} \) the fluid density, \( \bar{c}_{pm} \) the fluid mean specific heat, \( \bar{\mu} \) the fluid viscosity and \( \bar{k} \) the fluid thermal conductivity. The governing equations in tensor notation using the above definitions can be written as follows:

**CONTINUITY:**

\[
\rho_t + (\rho u_i)_{,i} = 0 \quad \text{eqn. 2.2}
\]

**MOMENTUM:**

\[
(\rho u_i)_{,t} + (\rho u_i u_j)_{,j} = -p_{,i} - \rho g_i + (\sigma_{ij})_{,j} \quad \text{eqn. 2.3}
\]

**ENERGY:**

\[
(\rho c_{pm} T)_{,t} + (\rho u_i c_{pm} T)_{,i} = (k T_{,i})_{,i} + \mu \Phi + P u_i_{,i} \quad \text{eqn. 2.4}
\]

where the \( t \) subscript denotes derivatives with respect to time. The dimensionless shear stress tensor \( \sigma_{ij} \), \( c_{pm} \) and the dissipation function \( \Phi \) are given respectively by:

\[
\sigma_{ij} = \mu (u_{i,j} + u_{j,i} - \frac{2}{3} \delta_{ij} u_{k,k})
\]
\[ c_{pm} = \frac{1}{T-1} \int_{1}^{T} c_p dT \quad \text{eqn. 2.5} \]

\[ \Phi = 2(u^2_{i,j}) \delta_{ij} + [u_{i,j}(1 - \delta_{ij})]^2 - \frac{2}{3} (u_{i,i})^2 \]

where \( \delta_{ij} \) is the Kronecker delta function. It should be noted here that the program neglects the viscous dissipation.

The basic numerical method is developed using the control volume approach described by Patankar [Ref. 1]. As stated in Ref. [1], the general form of the energy, momentum and continuity equation is:

\[ \frac{\partial}{\partial t} [\rho \phi] + \nabla \cdot (\rho \vec{u} \phi) = \nabla \cdot (\Gamma \nabla \phi) + S \quad \text{eqn. 2.6} \]

where \( \phi \) is the dependent variable. The diffusion coefficient \( \Gamma \), and \( S \) correspond to the specific meaning of \( \phi \). The discretized form of eqn. 1 may in general be expressed as:

\[ A_p \phi = A_E \phi_E + A_W \phi_W + A_N \phi_N + A_S \phi_S + A_F \phi_F + A_B \phi_B + S \quad \text{eqn. 2.7} \]

where the subscript \( P \) refers to the center of the control volume and the subscripts \( E, W, N, S, F, B \) refer to quantities determined for points at the center of the East, West, North, South, Forward, and Bottom neighboring control volumes of \( P \). \( S \) can be viewed as a source term and a collection of quantities that do not neatly fit into the coefficients for
the center and neighboring grid points. The coefficients $A_p$ through $A_s$ and $S$ are determined by the specific differencing scheme used.

The approach espoused by Patankar utilizes the 'centered grid' to calculate the dependent variables of temperature, pressure and density and the 'staggered grid' to calculate each component of velocity. In effect, the temperature, pressure and density calculations yield solutions for discrete points at the center of each centered control volume and the calculations for the three components of velocity give solutions for discrete points located at the face of each centered control volume. The energy equation is used to determine the temperature field. The momentum equations are coupled to the continuity equation to derive the velocity field and the pressure field. This is done because of the difficulty in solving for the pressure gradient which appears in the momentum equation. This particular procedure is clearly explained in Refs. 1 and 14. The continuity equation actually functions as an extension of the momentum equation to determine a pressure correction for each control volume. This is termed the 'local' pressure correction. These local pressure corrections are then used to both complete the velocity calculation and update the value for pressure at the nodes to which they apply. The perfect gas equation of state is used to derive the density field.
Figure 2.1 QUICK Scheme Portrayal

The pressure field which results from the method described
above is not, in general, correct as pointed out by Nicolette et al. [Ref. 11]. As explained by Patankar [Refs. 1,14], the local pressure correction is derived by demanding that it satisfy the continuity equation and eliminate the source term for each control volume. This provides for the local pressure variation in the compartment. However, it does not provide for determining any changes to the overall (global) pressure level in the space. Since the density calculations are dependent on an accurate assessment of the true value of the pressure at each node, an additional correction for the pressure field is required. This is provided by the global pressure routine which is described in section E.

The application of the QUICK finite difference technique to the governing equations is described in great detail by Raycraft and Houck [Refs 21,22]. Their formulation is explained in terms of a general coordinate system and can be applied directly to the derivation of the discretization equations used in this program. The derivation need not be repeated here. More apropos to this thesis is a discussion of the numerical properties of the QUICK method.

The method is described in general by Leonard [Refs. 12,14]. It is an explicit finite difference algorithm designed for highly convective flow. A one dimensional approach is employed for analyzing stability constraints and truncation errors. For one dimension and constant density, eqn. 2.6 reduces to the following:
\[ \frac{\partial \phi}{\partial t} = -\frac{\partial u \phi}{\partial x} + \frac{\partial}{\partial x} \Gamma \frac{\partial \phi}{\partial x} + S \]  \hspace{1cm} \text{eqn. 2.8} 

where symbols have the same meaning as described for eqn 2.6. After integration this equation can be expressed as shown by Leonard [Ref. 14] and repeated here for convenience.

\[ \phi_{i+1}^{n+1} = \phi_i^n + c_l^n \phi_i^n - c_r^n \phi_r^n + \left[ \alpha_r^n \left( \frac{\partial \phi}{\partial x} \right)_r^n - \alpha_l^n \left( \frac{\partial \phi}{\partial x} \right)_l^n \right] + \Delta t S_i \]  \hspace{1cm} \text{eqn. 2.9} 

where \( c \) represents the Courant number and \( \alpha \) represents the diffusion parameter:

\[ c = u \frac{\Delta t}{\Delta x} \]  \hspace{1cm} \alpha = \Gamma \frac{\Delta t}{\Delta x} \]  \hspace{1cm} \text{eqn. 2.10} 

Figure 2.1 serves to illustrate the meaning of the subscripts. \( r \) denotes the interface to the right of point \( i \) and \( l \) to the left. \( S \) represents the space time averaged source term. The goal of the numerical interpolation scheme is then to accurately calculate the values for \( \phi \) and its gradient at the interfaces. As the name implies, the QUICK method uses a quadratic interpolation involving three nodes, the two immediately adjacent to the interface and then the next node upstream depending on the direction of the velocity at the interface. Dropping the superscript \( n \), this results in the following expressions for \( \phi \):
\[ \phi_i = \frac{1}{2} (\phi_{i+1} + \phi_{i-1}) - \frac{1}{8} CURV \Delta x^2 \]  
\text{eqn. 2.11}

where

\[ CURV = \frac{\phi_i - 2\phi_{i-1} + \phi_{i-2}}{\Delta x^2} \quad \text{if } u_j > 0 \]  
\text{eqn. 2.12}

\[ CURV = \frac{\phi_{i+1} - 2\phi_{i+1} + \phi_{i-1}}{\Delta x^2} \quad \text{if } u_j < 0 \]  
\text{eqn. 2.13}

The expression for the gradient term is equivalent to a central differencing between the points \( i-1 \) and \( i \):

\[ \left( \frac{\partial \phi}{\partial x} \right)_i = \frac{\phi_i - \phi_{i-1}}{\Delta x} \]  
\text{eqn. 2.13}

The formulation for the right face is similar and can be correctly displayed by adding the number one to each of the subscripts and changing the \( l \) to an \( r \) in eqns. 2.11-2.14.

Because the gradient term is expressed by what amounts to a central differencing technique, the QUICK scheme is formally second order \( (O(\Delta x)^2) \) in the spatial variable [Refs 14,16]. However for conditions in which the convective transport is dominant over diffusive transport, the scheme becomes essentially third order accurate in the spatial variable. shown by Leonard [Ref. 12], a Taylor series expansion around \( i-1 \) reveals that:

\[ \phi_i = \phi_{i(exact)} + \frac{1}{16} \left( \frac{\partial^3 \phi}{\partial x^3} \right)_i \Delta x^3 + H.O.T \]  
\text{eqn. 2.14}

The method is explicit and the truncation error in time is of
The method is therefore not really suited for particularly unsteady behavior.

The stability constraints on the time step are described by Leonard [Ref. 14] using a Fourier-von Neumann analysis of a one dimensional, source free finite difference equation for constant values of $u$ and $\Gamma$. The solution for $\phi$ is considered to be of the form:

$$\phi = A(t)e^{ikAx}$$

where $k$ is the wave number. Eqn 2.15 is substituted into eqn 2.9 and an expression for the ratio of the amplitudes $(A(t+1)/A(t))$ is found. Furthermore a cell Peclet number is defined as $P_{cell} = c/\alpha$. The result is that the restrictions on the time step can be expressed as:

$$\Delta t \leq \frac{2\Delta x^2}{4\Gamma + u\Delta x}$$

and

$$c \leq \frac{2}{P_{cell}} + \frac{\pi^2}{2N^2}$$

where $N$ is the number of grid subdivisions in the given direction. These restrictions correspond to the low convection and high convection regimes respectively. The restriction given in eqn. 2.17 is actually an approximation to the formal Von Neumann criteria. The Von Neumann method places no restrictions on the size of the domain and considers waves of
infinite length as part of the solution for a given variable. The resulting expression for the time step is much smaller. In actual practice a grid size is finite and only waves of a finite length will enter into the solution. The second restriction results from this more realistic approach.

Although the entire discussion was for a one dimensional case, it is not inapplicable to the three dimensional code used here. This is because the one dimensional QUICK scheme is applied individually to each dimension to determine values of the given variable at the faces of the control volume. It is therefore reasonable to assume that the code should be subject to the basic limitations described by Leonard. In applying the analysis in Chapter III, each dimension was analyzed and the time calculated by considering the most restrictive case and reducing by a factor of three. The application of eqns. 2.16 and 2.17 serve only as a basic estimate of the time step required for the given grid configuration. At the very least, the above discussion serves to define the relevant parameters affecting the stability and accuracy of the scheme.

Some mention of the impact of the implementation of boundary conditions on the stability and accuracy of the differencing scheme must also be made. For the open compartment, the boundary conditions are set by what amounts to a forward differencing scheme which is first order accurate in both the time and spatial variables [Ref. 16]. This has to be considered in designating the time step. Determination of
the grid spacing was in accordance with the considerations described by Patankar [Ref. 14]. This amounts to making trial runs and attempting to evaluate where finer grid spacing is required by analyzing the magnitude of the velocity fields developed as well as the solutions for the other dependent variables.

The description of the radiation model and stress calculations which are incorporated into the model of the compartment interior are identical to that given by Raycraft and Houck [Refs. 21,22]. The viscosity and conductivity are calculated using an algebraic model for turbulent flows and appears to be identical to that described by Nies [Ref. 20] and Raycraft [Ref. 22]. Boundary conditions and the global pressure correction routine merited much consideration in modifying this code and are dealt with separately in sections C and D of this chapter.

C. MODEL OF THE ENCLOSURE WALLS

Heat transfer through the enclosure walls is assumed to be one dimensional (normal to the plane of the wall). As can be seen from figure 2.2, three nodes and the ambient temperature are used to provide the temperatures at the outer face and the internal wall node. The equations used to derive an expression for $T_1$ are given in eqn. 2.18 where $h$ is the convection coefficient between the wall and the ambient air. It is made a constant and assigned a value indicative of natural
convection.

\[ q''_{wall} = h(T_1 - T_w) \]

\[ q''_{wall} = -k_2 \frac{(T_2 - T_1)}{DXI} \]  

eqn. 2.18

The equation used to solve for \( T_2 \) is:

\[
\rho C_{pm} [T_2 - T_{2,old}] \frac{Vol}{\Delta t} = k_2 \frac{(T_1 - T_2)}{DXI} \Delta Z \Delta Y + k_e \frac{(T_3 - T_2)}{DXI} \Delta Z \Delta Y + q_r \]  

eqn. 2.19

where \( k_e \) is the geometric mean between \( k_2 \) and \( k_3 \) (the conductivity of the wall and air respectively). \( q_r \) is the radiative heat transfer from the fire to the wall control volume. The value of \( T_2 \) is used in the finite difference scheme for the compartment interior and the value of \( T_3 \) is calculated in the differencing scheme for the interior.

In the radiative heat transfer calculation, the surfaces of the enclosure are considered to be gray so that their absorptivity is equal to their emissivity. Only radiative heat transfer from the fire to the enclosure walls is considered (for the case in which there are no solids present in the compartment) and air is a non participating medium. The vent surface area is modeled as a black body of ambient temperature and the absorptivity is equal to unity. This heat transfer does not play a role in the derivation of \( T_2 \). \( T_2 \) in the vent area is provided by the boundary conditions. The radiative
heat transfer calculation is still made but the results are stored separately and then incorporated into the energy balance for the system.

![Diagram of conduction model](image)

Figure 2.2 Conduction Model
D. INITIAL AND BOUNDARY CONDITIONS

The initial conditions for the model are a quiescent air mass and the entire compartment in equilibrium with the ambient conditions. All velocity components are set to zero. The pressure and temperature is that of the ambient. The equilibrium pressure and density fields are calculated using the hydrostatic approximation:

\[ P = P_0 \exp \left( \frac{gz}{RT_A} \right) \]  \text{ eqn. 2.20}

Pressure field corrections are applied relative to the equilibrium quantities.

Boundary conditions are complicated somewhat by the use of the staggered grid and the combination of the conduction model with the compartment interior model. Figure 2.3 is a two dimensional view of the boundary and node placement on the west wall of the compartment. The boundary conditions can be summed up by the following statements although they require explanation. The subscript \( b \) denotes the boundary.

**AT ENCLOSURE WALLS**

\[ \vec{v}_b = 0 \]  \text{ eqn. 2.21}

\[ T_b = T_{amb} \]
IN THE VENT AREA

\[
\left( \frac{\partial v}{\partial n} \right)_b = 0
\]

\[
P_b = P_{amb}
\]

\[
T_b = T_{amb} \quad u_b > 0
\]

\[
T_b = T_{interior} \quad u_b < 0
\]

1. Closed Compartment

The temperature field for the entire enclosure (walls included) is established through a combination of the conduction model for the walls and the finite difference algorithms for the space within the enclosure walls. As was pointed out in the conduction model discussion, the boundary value used in the finite difference equations is provided by the conduction equations. Therefore the temperature boundary value for the entire system would be the value of temperature of the air outside the compartment.

The momentum equation is coupled to the continuity equation and the conditions for velocity are therefore intertwined with those for the pressure correction. The grid around the west wall is depicted in figure 2.3. The first u components in the interior are located on the inner face of the wall and the calculational control volumes are centered around the column of nodes that are vertically in line with the \( xs(i+1,j) \) node. This is not the case for the v components, nodes for which fall on either side of the face of the wall. The method followed in the program is to manipulate the
coefficients that are in the form of eqn. 2.7. Referring to figure 2.3, the equation for the v component of velocity is:

$$A_p V_p = A_w V_w + A_E V_E + A_N V_N + A_S V_S + S$$  \hspace{1cm} \text{eqn 2.23}$$

where the points P,W,E,N,S correspond to points ys(i,j), ys(i+1,j), ys(i-1,j), ys(i,j+1), and ys(i,j-1) respectively of figure 2.3. Although not derived in this thesis, it should be understood that the coefficient for point P includes the coefficients on the right hand side of the equation. Because $V_p$ is in the wall, the coefficients on the right hand side of eqn. 2.23 are set to zero and $A_p$ is assigned an artificially large value which is the semi-implicit method of setting the value of velocities for nodes inside of solids to zero. The no slip condition is implemented for the next line of nodes to the east of ys(i,j). This is approximated by setting the condition $V(i+1,j) = -V(i,j)$. The following manipulation is then made:

$$A_p V_p = A_w V_w + A_E V_E + A_N V_N + A_S V_S$$

$$V_p = -V_w$$ \hspace{1cm} \text{eqn 2.24}$$

$$(A_p + A_w) V_p = A_E V_E + A_N V_N + A_S V_S$$

where the subscripts P,W,E,N,S now refer to the nodes ys(i+1,j), ys(i,j), ys(i+2,j), ys(i+1,j+1), and ys(i+1,j-1) respectively. For the u component of velocity, the coefficients for the nodes on the inner wall face such as
xs(i+1,j) are treated in the same manner as in equation 2.23. The coefficients for the next line of nodes to the east are dealt with in the manner described by eqn. 2.24.

\[ xs(i+1,j) \]

The pressure correction calculational control volumes
are centered about the cv nodes (refer to figure 2.3). For the pressure correction calculations, the coefficients of interior compartment nodes which involve nodes in the wall are dealt with using the semi-implicit method. The $A_w$ coefficients for the first line of nodes inside the compartment are set to zero.

2. Open Compartment

Where a wall exists, the boundary conditions are implemented as described for the closed compartment. For the vented area the boundary value for temperature is designated depending on the direction of the component of velocity which is normal to the vent. The calculational control volumes for temperature are centered about the cv nodes. The nodes that fall on the boundary for the energy equation are those which are vertically in line with B1 in figure 2.4. If the flow is into the compartment (determined by whether the $u$ components of velocity calculated for the nodes vertically in line with B2 in figure 2.4 are positive or negative) then the boundary value is set equal to the ambient temperature. If the flow is out of the compartment then the boundary value for is set equal to the node immediately to the EAST (inside the compartment) of it.

For the vent area the gradient of all components of velocity in the direction normal to the plane of the vent (east-west direction) is set to zero. For the $v$ component of
velocity, this corresponds to the nodes vertically in line with B1 in figure 2.4. For the u component, the first nodes in the calculational domain are vertically in line with B2 and therefore the zero gradient specification is applied there.

Using the u component for an example, the manipulation of coefficients proceeds as follows:
\[ A_p U_p = A_w U_w + A_E U_E + A_N U_N + A_S U_S \]

\[
\frac{\Delta U}{\Delta x} = 0 \quad \text{so,} \\
V_p = V_w \\
(A_p - A_w) U_p = A_E U_E + A_N U_N + A_S U_S
\]

The stipulation that the pressure outside the compartment does not rise requires that no pressure correction be developed for the first node in the vent area that is part of the calculational domain for the pressure correction. This corresponds to the nodes that are vertically in line with B1 in figure 2.4. The procedure is the same as that for eqn. 2.24.

E. GLOBAL PRESSURE ROUTINE

The basis for the global pressure correction which is calculated separately from the local pressure correction is that the transient term in the continuity equation can be manipulated to yield a correction for the overall pressure field as described by Nicollette et. al. [Ref. 11]. Nicollette’s formulation applied specifically to a closed compartment. The description which follows for the closed compartment parallels that of Nicollette. It was found necessary to try to extend this type of correction to the open compartment based on results observed during this thesis work.
1. Closed Compartment

In the formulation described by Nicollette [Ref. 11], the transient term for a fixed volume-fixed mass system can be expressed as:

\[ \frac{\partial}{\partial t} \sum \rho \Delta V = 0, \]

\[ \sum \rho^{(t+\Delta t)} \Delta V = \sum \rho_{eq} \Delta V \]

where \( V \) denotes volume. The density is a function of both pressure and temperature. The true value of the pressure and temperature at any point can be written as:

\[ P = P^* + P' \]

\[ T = T^* + T' \]

where the starred quantities are those calculated from the previous time step and the primed quantities are a correction. Nicollette's method is to first ignore the temperature correction and then to manipulate eqn 2.26 using the perfect gas law to provide a pressure correction which is then applied to each cell. The density field is then calculated and the temperature field iterated with the new values of density. The procedure provides for a more accurate assessment of the temperature and density fields prior to solving for the velocity field and local pressure correction.

2. Open Compartment

For the open compartment, the formulation of the global pressure correction routine for the closed compartment
is no longer valid. For one of the trial runs presented in Chapter III, the global routine was simply not applied, thinking that the results would not be markedly affected. From the analysis of that trial run, it was apparent that a global correction was required. An attempt was made to account for the mass convected from the compartment opening by modifying eqn. 2.26 as follows:

\[ \sum (\rho t) \Delta V = \sum \rho_{eq} \Delta V + \sum_{g} (\rho A \bar{v}_n)_{vent} \Delta t \]  

\text{eqn. 2.28}  

where the vent term represents the mass that has flowed from the vent. The outcome is discussed in Chapter III.
III. NUMERICAL RESULTS

A. BACKGROUND

The objective of the work beginning with Thorkildsen [Ref. 24] was to model a solid rocket propellant fire in a compartment in the enclosure described in chapter one. The results which were presented in Ref. 24 demonstrated the model's effectiveness only in modeling a very mild heat generation rate type fire (approximately 26 BTU/S or 27.4 KW). Instability problems were encountered in trying to increase the heat generation rate and the emphasis in Thorkildsen's work was therefore on the development of graphics programs to display data. These graphics programs were indispensable in analyzing the numerical experiments described herein. The work done by Nies, Raycraft, and Houck [Refs. 20-23] involved modeling of fires generated by fuels with a comparatively small heat of combustion and overall much smaller energy input rate into a compartment. The heat release rate of the type of fire considered here is approximately two orders of magnitude greater than those modeled previously. The results presented herein are considered preliminary in that no claim is made to have accurately modeled the China Lake test facility. The discussion in this presentation centers around the numerical experiments conducted in attempting to make this particular
code produce realistic outputs given the magnitude of the energy input into it and the attempt to incorporate an enclosure opening.

The first topic addressed in this chapter is the input of the heat release characteristics of the fire and the thermodynamic properties of the enclosure materials. The next issues that are discussed are the actions taken to prevent instability in the program. This includes the grid and time step utilized. Finally an analysis of the results is presented.

B. HEAT SOURCE AND INPUT PARAMETERS

The development of an algorithm to accurately model the characteristic heat release rate of a solid rocket propellant was not a priority in this thesis. Two factors that were considered were that the fuel is self oxidizing and therefore is relatively unaffected by the surrounding conditions and that the fuel almost instantaneously reaches its maximum burn rate. In view of these facts the burn rate was set for a linear increase until it reached its maximum rate. In Thorkildsen’s work [Ref. 24] the rate of the linear increase was set for a period of two seconds. For the runs conducted during this thesis the linear increase took place over the first eight seconds of fire time. The rate that energy was distributed into the compartment was modified by estimating the energy radiated from the source to the walls of the
compartment. This was done by summing up the radiation to the walls from the previous time step and subtracting it from the quantity calculated for dispersion into the interior compartment control volumes during the current time step. This was a feature of the program received from Notre Dame.

As a first approximation it was desired to get output for a 1.0 lbm/s (0.45 kg/s) burn rate. It was eventually found that 1.0 lbm/s was too high given the fuel's heat of combustion and burn rate characteristic input into the program. The significant properties input into the program are summarized in the following table.

**Table I MATERIAL PROPERTIES SUMMARY**

Discussion of mass burn rates will henceforth be made in English units. All other quantities will be discussed in SI units.
C. GRID and TIME STEP

The first step taken in attempting to derive output from the program for a large heat release rate was to refine the grid. In the beginning stages of the fire the largest components of velocity are in the vertical direction and the largest gradients are in the overhead and around the fire itself. This could be observed from the plots of the results from previous theses [Refs. 20-24]. Because the program could incorporate a non-uniform grid, it was decided to vary the grid spacing in the vertical direction throughout and then to also modify the grid spacing in the horizontal directions around the fire. Several variations were tried and the eventual outcome was a grid with one half foot spacing in the vertical direction from the floor to the overhead and one half foot spacing in both horizontal directions in the area of the fire. In addition extra nodes were incorporated into the vent area on the west wall. A plan view of the horizontal grid spacing is provided in figure 3.1. The energy input was distributed into a total of 24 control volumes stretching from 16 feet to 18 feet in the x direction, 8 feet to 10 feet in the y direction and 1 foot to 5.5 feet in the z direction. This is an area which is roughly 6 percent of the entire volume of the enclosure. The final result was a grid for the interior of the compartment of the size 25 by 25 by 20. Additional nodes are required for the walls so the total grid used to solve the problem was 30 by 30 by 25. Each run in the
analysis that follows was run with this 30 by 30 by 25 nonuniform grid.

The criterion for the time step was outlined in chapter two. This can serve only as a general guide because the local cell Peclet numbers are changing throughout the problem. In addition the diffusion parameters of viscosity and conductivity are variable, the grid is nonuniform, and the treatment of boundary conditions entails greater inaccuracies. What results is a very general estimate indeed. However, choosing to use the parameters that affect the calculation of the momentum equation (kinematic viscosity) and then evaluating eqns. 2.16 and 2.17 results in a time step criterion of less than 0.66 seconds and 0.0026341 seconds respectively. The following parameters were used to arrive at this conclusion:

\[
v = 1.56E-4 \frac{ft^2}{s}
\]
\[
u = 1 \frac{ft}{s}
\]
\[
\Delta x = 1 \text{ ft}
\]
\[
N_{(NR \text{ grid points})} = 25
\]

In running the numerical experiments it was found that time steps of up to 0.0125 seconds provided consistent results but this depended on the type of problem run. Each run is annotated with the time steps used.
D. RESULTS

The results of each trial are discussed individually. Plots of various quantities are given for similar locations in the compartment for comparison purposes. Only a small amount of information that can be output from the program is included herein. The atmospheric pressure in the compartment varied by less than one percent from the bottom of the compartment to the top for any specific time. This serves to demonstrate the reason why it would be very difficult to find the local pressure variation for use in the momentum equations by using the perfect gas law. The pressure graphs indicate the atmospheric pressure variation in the compartment with time. The isotherm plot and thermocouple units are degrees celsius, the velocity is in cm/s and the pressure plots in atmospheres. The heat input rate to the compartment varied due to the attempt to consider the radiative transfer as explained previously. The heat input rate in kilowatts is therefore given for each trial except the first.

Trial 1 demonstrates some of the stability problems that were encountered in running the program. Trial 2 was a run for a closed compartment. Trial 3 was intended to simulate the open compartment. No global pressure correction was applied in trial three. Because of unexpected results in trial 3, a run was conducted (trial 4) for a closed compartment with no global pressure correction applied. Trials 5 and 6 were run due to observations made in runs 2 and 3. The orientation for
viewing the plots is given in figure 3.2.

A note of caution is made concerning the CPU run times given in the analysis. To say that a certain number of CPU seconds are required for a second of fire time is quite inaccurate. The solution procedure is an iterative one - some time steps may require far more computational effort than others. Larger fires are more difficult to solve for than smaller ones. The CPU time listed should therefore be the basis for only a very general comparison between runs. The computer used was the AMDAHL MODEL 5995-700A located at NPGS.

1. Trial 1

In this trial the results from a run in which the burn rate was set to 1.0 lbm/s illustrate some of the difficulties in getting the program to perform for a high energy input level. The velocity and isotherm plots are given in figures 3.5 to 3.7. The intent was to burn approximately 25 lbm of fuel and to record the buildup of the fire and the subsequent post fire phase in an open compartment. The input level was ramped up over a period of eight seconds to its maximum rate of 2745 KW. At the 10 second mark areas in the compartment had already reached temperatures in excess of 4000 °C. The fire burn rate was kept at that level until the 25 second mark at which time the energy input was set to zero. Figure 3.6 shows the compartment temperatures exactly at this time. The isotherm indicates that the compartment air mass is almost
uniformly above the 2000 degree mark and it has become difficult to locate the fire at that point. Figure 3.7 shows the same elevation view 1.3 seconds later. Most areas are already 2000 degrees cooler, a situation which is not believable. The velocity plot indicates a large change in conditions at the vent area. The excess mass term generated in the continuity equation calculations exceeded its maximum limit at the 26.8 second mark.

One lesson learned from this and other runs including those for a closed compartment with a global pressure correction applied were that the numerical model has difficulty incorporating almost instantaneous changes in energy input level. This is undoubtedly due to the fact that such changes lead to severe gradients and the existing grid refinement becomes inadequate for resolving these gradients.

The other lesson learned was that a burn rate of 1.0 lbm/s appears excessive given the heat of combustion used in these trials. The temperature field reaches levels in excess of 4000 degrees very quickly in both the open and closed compartment. Therefore runs are subsequently conducted at half that burn rate.

2. Trial 2

Trial two was for a closed compartment with a mass burn rate of 0.5 lbm/s for 60 seconds. The time step utilized was 0.003125 seconds for the first 10 seconds, 0.009375
seconds for the period from 10 to 20 seconds and then 0.0125 seconds until completion. The total amount of CPU time required was 29865 seconds. The pressure and heat input curves are presented in figure 3.3. Figures 3.8 through 3.15 present the velocity and isotherm plots. The velocity plots appear to concur with the isotherm plots as the fire progresses. The elevation view for Y equal to 8 feet (figure 3.8) which cuts directly through the fire shows the upward plume growing stronger with time. Other velocity plots show a circulation pattern around the compartment. By 60 seconds the entire air mass above the midlevel of the compartment is above 1000 C. The fire location is becoming more difficult to pinpoint from views above the compartment midlevel. A much colder and mostly stagnant air mass can be seen at the bottom of the compartment. This gradually becomes a much smaller percentage of the compartment as time progresses.

One of the most glaring peculiarities of the isotherm plots are the relatively cool areas around the compartment periphery. In fact an analysis showed that the maximum wall temperature around the compartment was 98 C, a situation which was hardly believable. A simple analysis of the conduction model reveals a serious defect. The resistance to heat transfer at the wall's interface with the outside air can be compared with the inner wall interface with the interior compartment air using a simple electrical circuit analogy (figure 3.16). Recalling from Chapter II that the conductivity
at the inner wall interface was given by the geometric mean between the wall node conductivity and the first node in the compartment, the resistances can be expressed as follows:

OUTER WALL:

\[ R_{outer} = \frac{1}{h} \]

where \( h \) denotes the heat transfer coefficient.

INNER WALL:

\[ R_{inner} = \frac{L}{k_e} \]

where \( L \) is the length between the wall node and the first node in the space.

At the start of the problem the value for the outer resistance was found to be 0.012 K/W he inner resistance was found to be about 471 K/W. In this model, heat transfer to the air in the compartment is by conduction only. The very small value for the air conductivity dominates the geometric mean calculation and a large resistance to heat transfer between the surface of the wall and the inner compartment results. Very little heat transfer occurs from the air to the walls. This has a very deleterious effect on the energy balance in the compartment and makes the solutions highly suspect. This basic problem was not realized until run 4 had been completed.
3. **Trial 3**

Trial 3 was for an open compartment and was run without using the global pressure correction. A 4 ft by 4 ft opening was placed in the west wall. The burn rate was 0.5 lbm/s and the time step was 0.003125 seconds for the entire run (60 seconds). The amount of CPU time required was 181000 CPU seconds. The pressure and heat rate input curves are shown in figure 3.3. The velocity and isotherm plots are given in figures 3.17 to 3.24.

The velocity plots appear to support the information portrayed by the isotherm plots as the fire progresses. There is a strong mass outflow from the compartment during the entire run. A strong buoyant updraft is shown in the fire’s vicinity. Once again the periphery of the compartment is relatively cool. In fact the vent area is much hotter than the adjacent walls.

Upon comparison of the open compartment with the closed compartment it is immediately evident that the results are not what might be expected. The open compartment is several hundred degrees hotter than the closed compartment. The pressure in the open compartment remained at nearly atmospheric pressure while the closed compartment showed almost a linear increase. It is seen that the application of the global pressure correction has major consequences for the solution arrived at. A check on the density fields calculated for the two runs and the use of the perfect gas law serve to
illustrate what is occurring. At time 42 seconds representative values of the density field in the two compartments was as follows:

<table>
<thead>
<tr>
<th>HEIGHT</th>
<th>OPEN COMPARTMENT</th>
<th>CLOSED COMPARTMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 ft</td>
<td>0.867E-03</td>
<td>0.220E-02</td>
</tr>
<tr>
<td>5 ft</td>
<td>0.242E-03</td>
<td>0.810E-03</td>
</tr>
<tr>
<td>9 ft</td>
<td>0.144E-03</td>
<td>0.625E-03</td>
</tr>
</tbody>
</table>

The pressure in the closed compartment was 2.545 atmospheres while the open compartment was at 1.0008 atmospheres. Thus the pressure in the closed compartment was 2.54 times greater than that of the open compartment and the density was from 2.5 to 4.3 times greater. Applying the perfect gas law to the open and closed compartments respectively:

\[ P_o = \rho_o R T_o \]

\[ P_c = \rho_c R T_c \]

Thus,

\[ \frac{P_c}{P_o} = \frac{\rho_c}{\rho_o} \frac{T_c}{T_o} \]

\[ T_c = \frac{2.5}{3.5} T_o = \frac{5}{7} T_o \]

This was arrived at by approximating the pressure and the density of the closed compartment to be 2.5 and 3.5 that of
the open compartment respectively. This analysis is far oversimplified but it serves to emphasize the difference between the two solutions and the importance of the pressure field calculation. In general, the air density in the open compartment was less than that of the closed.

The heat input rate in this trial run becomes significantly less than that of the closed compartment as time progresses. The reason is that the radiative heat transfer is much higher and the energy is being continually squandered to the air surrounding the compartment due to the hole in the wall and the conduction model problem mentioned in the trial two run. However, due to the difference in pressure fields the compartment is hotter which serves to increase the radiative transfer. The radiative heat transfer is input back into the heat input loop and the result is the curve of figure 3.3.

Before beginning discussion on trial run 4, one aspect of the open compartment run which needs to be pointed out is the hot spot in the area directly opposite the hole in the wall closest to the fire (figure 3.24). The hot spot does not appear in the closed compartment. In run number 6 the same phenomenon is observed although the flow at the open vent is much different.

4. Trial 4

Trial 4 was conducted to investigate the effect of the absence of the global pressure correction routine on the
closed compartment. The total time run was therefore only 20 seconds. The heat input rate and the pressure curves are given in figures 3.3. The isotherm and velocity plots are given in figures 3.25 to 3.28.

The result of the run was that the pressure field was markedly different from that of the closed compartment with the global correction applied. The pressure rises but not nearly as significantly as in the trial 2 run. The isotherm plot at 20 seconds is similar but the magnitude of the temperature field is higher. From this run it was decided to attempt to incorporate a global pressure correction for the open compartment.

5. Trial 5

The intent of trial run 5 was to experiment with the conduction model so that the resistance between the wall and the interior compartment was of about of the same magnitude as that between the wall and the exterior of the compartment. The geometric mean conductivity for the inner wall was increased by a factor of 1000.

For this run a time step of 0.00935 seconds was used for the first 20 seconds and 0.0125 seconds was used for the rest of the run. The heat input and pressure curves are as given in figure 3.4. The total CPU time required was 44250 seconds.

Since the intent of this run was to investigate the
results of an alteration to the conduction model on the heat transfer to the wall, a minimum of plots are provided (figures 3.29 to 3.31). The maximum temperatures of the walls have now increased dramatically. At 60 seconds the wall closest to the fire has reached over 1000 C in spots. The isotherms indicate that the area near the walls are several hundred degrees hotter than that of trial 2. A close inspection shows that the periphery of the compartment is now mostly blue rather than black indicating a marked temperature rise. However, it still appears that the effect of radiative heat transfer is not being registered in the walls. The bottom wall, for instance, is hardly above ambient (maximum 70 degrees) at 60 seconds. It would be expected that there should be some indication of heat being transferred to the air from the floor but such is not the case. The heat transfer is apparently mostly from that convected from the fire to the vicinity of the walls.

6. Trial 6

The final trial was for an open compartment with the global pressure correction applied to the interior and with the geometric mean conductivity of the inner walls increased by a factor of 1000 as in trial 5. The hole was of the same size as that used in trial 3. A time step of 0.00625 seconds was used for the entire run. The total CPU time required was 79285 seconds. The heat input rate and pressure curves are given in figure 3.4. The velocity and isotherm plots are given.
in figures 3.32 to 3.36.

The result of the application of the global pressure correction by incorporating the mass transfer from the compartment is seen in the pressure curve. The pressure in the open compartment is higher than that of the closed compartment at 60 seconds. The velocity diagrams show a slight inflow at the bottom of the opening in the wall and no flow at the top portion of the opening. It is difficult to distinguish any flow through the opening. The isotherm plots however, indicate that the temperature field is slightly cooler than for the open compartment. The fact that there is an opening in the wall opposite the fire cannot be distinguished from the isotherm plots. However, the hot spot in the wall adjacent to the fire has reappeared and is similar to that alluded to in trial 3.

The boundary conditions implemented for this run were identical to that of the run in trial 3. The global pressure correction was applied to only those control volumes in the compartment. It was not applied to the control volumes immediately outside of the compartment interior. The pressure calculated for the nodes outside of the boundary was 1 atmosphere (as intended) after 60 seconds had elapsed. The pressure of the nodes immediately inside the boundary was over 3 atmospheres. Surely some outward flow should have developed. This aspect of the analysis is still being investigated.

IV. CONCLUSIONS AND RECOMMENDATIONS

The effort expended in this thesis was fruitful in that it established some guidelines and background for utilizing this program to model a fire from a large magnitude heat source. However, it appears that more questions have been raised than solutions. Deficiencies in the numerical model could be expected to become more evident when subjecting it to a larger scale fire. Stated first are a number of conclusions and then recommendations.

A. CONCLUSIONS

1. Use of a nonuniform grid is necessary. A compromise between computational time and grid size must be made. The runs conducted in this thesis for the closed compartment did not require as many nodes as were used.

2. Time steps should have been increased for these runs.

3. The determination of the overall pressure field affects the solution markedly. This is illustrated by comparison of runs using the global pressure correction routine with those that do not.

4. The problems experienced in this thesis work concerning the conduction model were most likely due to placing the first nodes inside the compartment too far away from the walls. Finer grid refinement in the area adjacent to the walls should correct these problems.

5. Location of the fire affects the solution, as should be expected. The source was placed one foot above the deck and at least two feet away from the walls to ensure that view factors would be calculated to each part of the compartment. Different locations of the fire may require different grid discretization.
6. Input into the program is in English units. Output is in SI units. The NCAR graphics programs utilize SI units. It would be more convenient to discuss input and output in the same units.

7. The procedure is susceptible to instability given large transients. This was observed in trying to input the maximum heat input over a period of two seconds and again when the source was instantaneously extinguished as in trial one.

8. It should be noted that provision is made for installation of solids in the compartment but no provision is made for their instantaneous combustion.

9. The amount of data that may be output from the program is impressive. The most interesting portions of the fire runs are within the first 20 seconds. The analysis will be valuable because there is an ability to see clearly where hot spots develop and in general, the isotherm plots fit with the velocity plots.

10. View factor and radiation heat transfer routines appear correct. No in depth investigation of these were made. No investigation of the viscosity or stress calculations was conducted.

B. RECOMMENDATIONS

1. The conduction model/interior compartment model interface problem experienced in this thesis need to be resolved. Placing nodes very near the walls should improve the situation.

2. The formulation of the global pressure correction routine for the open compartment should be reviewed.

3. The program includes a smoke generation subroutine. This should eventually be utilized.

4. A maximum cell Peclet number calculation should be incorporated into the scheme. The procedure which appears in appendix C of the program used in Nies’ thesis [ref. 20] could serve as guidance.

5. The numerical model results should be compared with empirical data after the resolution of the conduction model problems experienced in this thesis.
APPENDIX A. PROGRAM FLOW CHART

The figures on the following pages provide the program flow chart for the program listed in Appendix B. This flow chart is not entirely complete but the diagrams are accurate to the extent of what they portray.

*****************************************************************************
SUBROUTINE GLOBE
*****************************************************************************
*THIS SUBROUTINE CALCULATES THE GLOBAL PRESSURE CORRECTION, WHEREBY THE
*PRESSURE MATRIX IS UPDATED.
*
*VARIABLES USED ARE:
* SUMT = SUM OF TEMPERATURES

145
* SUMPT = SUM OF PRESSURE OVER TEMPERATURE
* SUMPET = SUM OF EQUILIBRIUM PRESSURE OVER TEMP
* UGRT = CONSTANT (FROM SUBROUTINE INIT)
* PCORR = PRESSURE CORRECTION

*Impossible to format the code properly, but it seems to be a Fortran subroutine. The subroutine appears to calculate thermodynamic properties. The comments in the code indicate that the subroutine calculates the sum of pressure over temperature, sum of equilibrium pressure over temperature, and constant from subroutine INIT. The subroutine also calculates pressure correction and applies it to the pressure field.

The code includes common blocks and a series of nested DO loops that iterate over the grid points. The loops are used to calculate the sum of pressure and equilibrium pressure, as well as the product of volume and temperature. The subroutine concludes with the application of a pressure correction and a conditional branch that branches to different sections of the code based on the value of NVENT.
